Comparative Effectiveness and Personalized Medicine Research Using Real-World Data

Thomas P. A. Debray, Tri-Long Nguyen, and Robert W. Platt

5/3/23

Table of contents

1 Preface

Thomas Debray (Smart Data Analysis and Statistics B.V.)

This book provides practical guidance for estimating the effectiveness of treatments in real-world populations. It explains how real-world data can directly be used or combined with other data sources to derive overall and individualized estimates of treatment effect. The book explains statistical methods for implementing bias adjustments, conducting evidence synthesis and individualizing treatment effect, whilst also providing illustrative examples and supporting software. The chapters and contents of the book are written by leading experts, with a track record in the generation and/or evaluation of real-world evidence.

This book is intended as a pivotal textbook for statisticians, epidemiologists, methodologists, regulators and/or regulatory scientists considering, undertaking or appraising the real-world evidence of treatment effectiveness. It covers key concepts and stages to derive and evaluate treatment effect estimates for entire populations and specific individuals. The book offers a conceptual framework towards estimating treatment effects at both the population and individualized level, where modelling methods may include traditional regression-based and machine learning methods.

Motivation

Although randomized clinical trials traditionally form the cornerstone of comparative effectiveness research, there is a growing demand to consider evidence from "real-world data" (RWD) in clinical decision-making. These data are often available from observational cohort studies, administrative databases, and patient registries, and may offer additional insights into the comparative effectiveness and safety of treatments. Yet, the analysis of RWD and the evaluation of real-world evidence face many operational and methodological challenges.

In this book, we aim to address three current needs. First, this book will offer the guidance that is currently lacking on assessing the quality of RWD and on implementing appropriate statistical methods to reduce bias of single study estimates of treatment effects. Second, this book will provide researchers with advanced approaches to pooling estimates from multiple non-randomized studies for which traditional evidence synthesis methods are not suitable. Finally,

to answer the growing need to translate average estimates of treatment effects to individualized clinical decision-making, this book will present recent methods for more tailored approaches where patient characteristics are used to derive their individualized prognosis and treatment benefit.

This book aims to explain key principles and state-of-the-art methods for deriving treatment effects in entire populations and specific individuals using RWD. It will not only discuss statistical theory by key experts in the field; it will also provide illustrative examples and practical guidance for implementation in R. In short, the book aims to prepare a new generation of researchers who wish to generate and integrate evidence from both randomized and non-randomized data sources to investigate the real-world effectiveness of treatments in populations and individual patients.

Contents

The book is divided into six sections:

1. **Introduction**. This section introduces the relevance of real-world data for conducting comparative effectiveness research, and discusses various concerns regarding their use.
2. **Principles of treatment effect estimation using real-world data**. In this section, we discuss key principles of treatment effect estimation in non-randomized data sources. We explain methods to adjust for confounding (including propensity score analysis and disease risk score analysis) and missing data when estimating the treatment effect for a specific (sub)population.
3. **Principles of evidence synthesis**. In this section, we discuss statistical methods for estimating the treatment effect using (individual participant and/or aggregate) data from multiple studies. To this purpose, key principles of meta-analysis are introduced and explained, including the standard fixed effect and random effects meta-analysis models, methods for individual patient data (IPD) meta-analysis, methods for network meta-analysis, and methods for data-driven and tailored bias adjustment.
4. **Advanced modelling issues for dealing with additional bias in both randomized and non-randomized data sources**. In this section, we discuss advanced statistical and machine learning methods for dealing with time-varying confounding, informative visit schedules, and measurement error.
5. **Individualizing treatment effects for personalized medicine**. In this section, we discuss statistical methods to estimate and evaluate individualized treatment effects.
6. Closing

2 Validity control and quality assessment of real-world data and real-world evidence

Christina ReadThomas Debray (Smart Data Analysis and Statistics B.V.)

```
library(readxl)
library(robvis)
```

The quality of real-world data is often suboptimal and can therefore lead to bias when generating real-world evidence (RWE). In this chapter, we will introduce key quality concerns of RWD, including their accuracy, completeness, and timeliness. Subsequently, we will discuss which steps can be taken to assess the quality of RWD, and determine their fitness for use. The chapter will also introduce directed acyclic graphs to explain how the analysis of RWD may be affected by different types of bias. We will put particular focus on confounding bias, selection bias, and information bias, and explain how these biases can be addressed by referring to specific chapters from the book. Finally, the chapter presents common quality appraisal tools that can be used to assess the quality of real-world evidence (for instance when conducting a systematic review).

A risk of bias assessment was conducted in the COVID-NMA review. We can create a summary table of risk of bias assessment and produce a traffic light plot as follows:

```
Risk_of_Bias <- read_excel("resources/RoB-covid.xlsx")

#creation of traffic light plot
trafficlight_rob <- rob_traffic_light(data = Risk_of_Bias, tool = "ROB2")
trafficlight_rob
```

3 Confounding adjustment using propensity score methods

Tammy Jiang (Biogen)
Thomas Debray (Smart Data Analysis and Statistics B.V.)

The purpose of this document is to provide example R code that demonstrates how to estimate the propensity score and implement matching, stratification, weighting, and regression adjustment for the continuous propensity score. In this example using simulated data, we have two disease modifying therapies (DMT1 and DMT0) and the outcome is the number of post-treatment multiple sclerosis relapses during follow-up. We will estimate the average treatment effect in the treated (ATT) using propensity score matching, stratification, and weighting. We will estimate the average treatment effect in the population (ATE) using regression adjustment for the continuous propensity score. The treatment effects can be interpreted as annualized relapse rate ratios (ARR).

We consider an example dataset with the following characteristics:

```
head(dat)
```

```
   age female prevDMTefficacy premedicalcost numSymptoms prerelapse_num
1:  50      1            None        3899.61           1              1
2:  51      0            None        9580.51           1              0
3:  56      0            None        4785.89           1              0
4:  44      1            None        8696.80           1              1
5:  63      0            None        2588.03           1              0
6:  28      1            None        5435.57           1              0
   treatment y      years      Iscore
1:      DMT1 0 1.78507871 Moderate A1
2:      DMT1 0 0.01368925     High A1
3:      DMT1 2 3.25530459     High A1
4:      DMT1 2 5.73853525     Neutral
5:      DMT1 0 1.31143053     High A1
6:      DMT1 0 0.59137577 Moderate A0
```

3.1 Comparing baseline characteristics

- `DMT1` is the treatment group and `DMT0` is the control group
- `prevDMTefficacy` is previous DMT efficacy (none, low efficacy, and medium/high efficacy)
- `prerelapse_num` is the number of previous MS relapses

	DMT0	DMT1
n	2300	7700
age (mean (SD))	51.39 (8.32)	44.25 (9.79)
female = 1 (%)	1671 (72.65)	5915 (76.82)
prevDMTefficacy (%)		
None	1247 (54.22)	3171 (41.18)
Low_efficacy	261 (11.35)	858 (11.14)
Medium_high_efficacy	792 (34.43)	3671 (47.68)
prerelapse_num (mean (SD))	0.39 (0.62)	0.46 (0.68)

3.2 Estimating the propensity score

3.2.1 Logistic regression

We sought to restore balance in the distribution of baseline covariates in patients treated with DMT1 (index treatment) and DMT0 (control tratment). We fit a multivariable logistic regression model in which treatment was regressed on baseline characteristics including age, sex, previous DMT efficacy, and previous number of relapses.

```
# Fit logistic regression model
ps.model <- glm(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                data = dat, family = binomial())

# Summary of logistic regression model
summary(ps.model)
```

```
Call:
glm(formula = treatment ~ age + female + prevDMTefficacy + prerelapse_num,
    family = binomial(), data = dat)

Deviance Residuals:
```

```
    Min       1Q   Median       3Q      Max
-2.7949   0.2585   0.5220   0.7478   1.5033

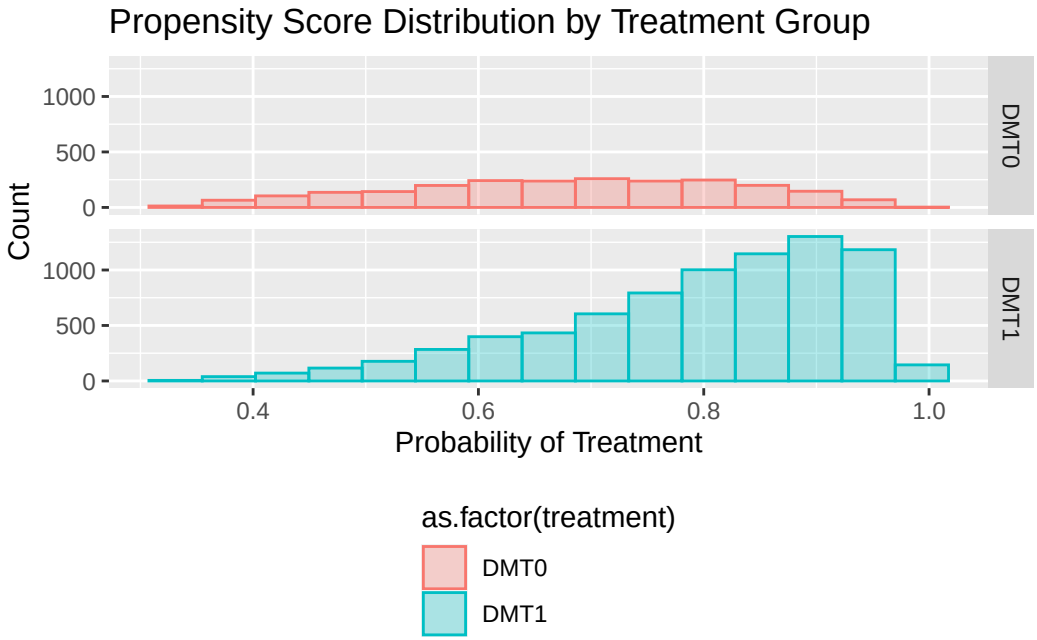
```

```r
# Extract propensity scores
dat$ps <- predict(ps.model, data = dat, type = "response")
```

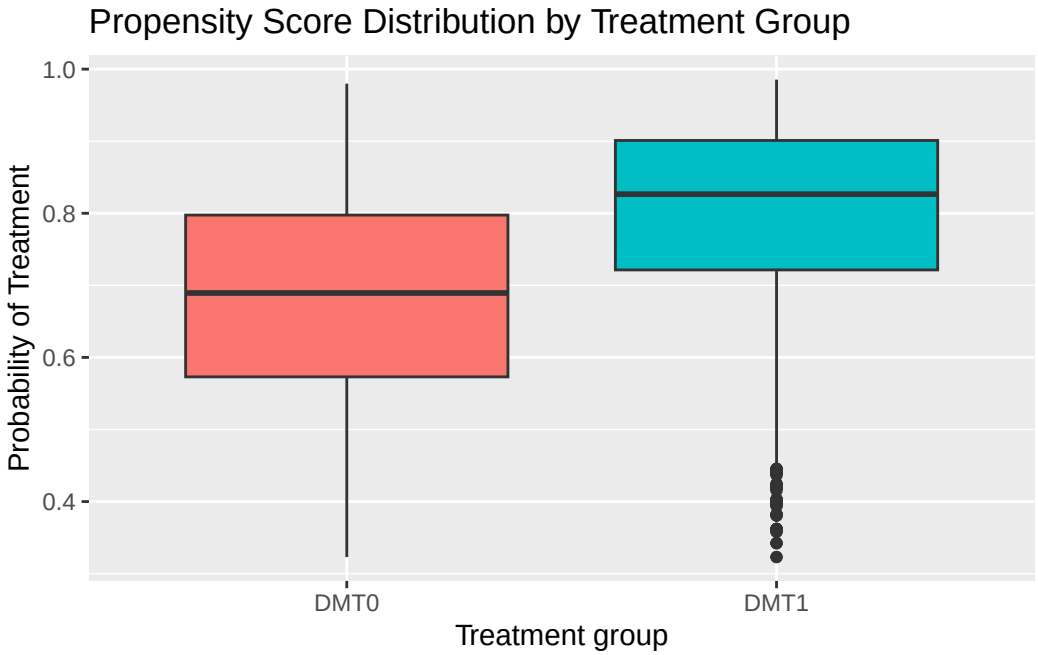
3.2.2 Assessing overlap

We examined the degree of overlap in the distribution of propensity scores across treatment groups using histograms and side-by-side box plots.

```r
# Histogram
ggplot(dat, aes(x = ps, fill = as.factor(treatment), color = as.factor(treatment))) +
  geom_histogram(alpha = 0.3, position='identity', bins = 15) +
  facet_grid(as.factor(treatment) ~ .) +
  xlab("Probability of Treatment") +
  ylab("Count") +
  ggtitle("Propensity Score Distribution by Treatment Group") +
  theme(legend.position = "bottom", legend.direction = "vertical")
```



```r
# Side-by-side box plots
ggplot(dat, aes(x=as.factor(treatment), y=ps, fill=as.factor(treatment))) +
  geom_boxplot() +
  ggtitle("Propensity Score Distribution by Treatment Group") +
  ylab("Probability of Treatment") +
  xlab("Treatment group") +
  theme(legend.position = "none")
```



```r
# Distribution of propensity scores by treatment groups
summary(dat$ps[dat$treatment == "DMT1"])
```

```
   Min. 1st Qu.  Median    Mean 3rd Qu.    Max.
0.3230  0.7214  0.8265  0.7970  0.9010  0.9854
```

```r
summary(dat$ps[dat$treatment == "DMT0"])
```

```
   Min. 1st Qu.  Median    Mean 3rd Qu.    Max.
0.3230  0.5730  0.6894  0.6795  0.7975  0.9799
```

3.3 Propensity score matching

3.3.1 1:1 Optimal full matching without replacement

```
library(MatchIt)

# Use MatchIt package for PS matching
opt <- matchit(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
               data = dat,
               method = "full",
               estimand = "ATT")

opt
```

```
A matchit object
 - method: Optimal full matching
 - distance: Propensity score
             - estimated with logistic regression
 - number of obs.: 10000 (original), 10000 (matched)
 - target estimand: ATT
 - covariates: age, female, prevDMTefficacy, prerelapse_num
```

3.3.2 Assess balance after matching

```
summary(opt)
```

```
Call:
matchit(formula = treatment ~ age + female + prevDMTefficacy +
    prerelapse_num, data = dat, method = "full", estimand = "ATT")

Summary of Balance for All Data:

3.3.3 Estimating the ATT

We can estimate the ATT in the matched sample using Poisson regression in which the number of post-treatment relapses is regressed on treatment status and follow-up time for each patient (captured by the variable `years`). More details are provided at https://cran.r-project.org/web/packages/MatchIt/vignettes/estimating-effects.html.

```
# Matched data
matched.data <- match.data(opt)

# Poisson regression model
opt.fit <- glm(y ~ treatment + offset(log(years)),
               family = poisson(link = "log"),
               data = matched.data,
               weights = weights)

# Treatment effect estimation
opt.comp <- comparisons(opt.fit,
                        variables = "treatment",
                        vcov = ~subclass,
                        newdata = subset(matched.data, treatment == "DMT1"),
                        wts = "weights",
                        transform_pre = "ratio")

opt.comp |> tidy()
```

```
# A tibble: 1 x 9
  type     term      contrast   estim~1 std.e~2 stati~3  p.value conf.~4 conf.~5
  <chr>    <chr>     <chr>        <dbl>   <dbl>   <dbl>    <dbl>   <dbl>   <dbl>
1 response treatment mean(DMT1~   0.761   0.100    7.59 3.21e-14   0.564   0.958
# ... with abbreviated variable names 1: estimate, 2: std.error, 3: statistic,
#   4: conf.low, 5: conf.high
```

As indicated in the summary output above, the annualized relapse rate ratio for DMT1 vs DMT0 among patients treated with DMT0 (ATT) is given as 0.76 with a 95% confidence interval ranging from 0.56 to 0.96.

3.4 Propensity score stratification

3.4.1 Divide sample into quintiles of propensity scores

We will form five mutually exclusive groups of the estimated propensity score.

```
# Create five strata
dat <- dat %>% mutate(ps.strata = cut(ps,
                                      breaks = c(quantile(ps, probs=seq(0,1,0.2))),
                                      labels = seq(1:5),
                                      include.lowest = TRUE))

# Number of patients in each stratum
table(dat$ps.strata)
```

```
   1    2    3    4    5
2002 2015 1991 1997 1995
```

3.4.2 Assess balance within each propensity score stratum

Within each propensity score stratum, treated and control patients should have similar values of the propensity score and the distribution of baseline covariates should be approximately balanced between treatment groups.

3.4.2.1 Propensity Score Stratum #1

```
tab1.strata1 <- CreateTableOne(vars, data = dat %>% filter(ps.strata == 1),
                               factorVars = c("female", "prevDMTefficacy"),
                               strata = "treatment", test = FALSE)

tab1.strata1.print <- print(tab1.strata1, catDigits = 2, contDigits = 2,
                            smd = TRUE)
```

	DMT0	DMT1	SMD

3.4.3 Estimating and pooling of stratum-specific treatment effects

The overall ATT across strata can be estimated by weighting stratum-specific estimates by the proportion of treated patients in each stratum over all treated patients in the sample.

We first define a function `att.strata.function()` to calculate stratum-specific estimates of the treatment effect:

```
att.strata.function <- function(data, stratum, confint = TRUE) {

  fit <- glm("y ~ treatment + offset(log(years))",
      family = poisson(link = "log"),
      data = data %>% filter(ps.strata == stratum))

  arr <- round(as.numeric(exp(coef(fit)["treatmentDMT1"])), digits = 3)
  ll <- ul <- NA

  if (confint) {
    ll <- round(exp(confint(fit))["treatmentDMT1",1], digits = 3)
    ul <- round(exp(confint(fit))["treatmentDMT1",2], digits = 3)
  }

  return(c("stratum" = stratum,
           "arr" = arr,
           "ci_lower"  = ll,
           "ci_upper"  = ul))
}

arr.strata <- as.data.frame(t(sapply(1:5, att.strata.function, data = dat)))
arr.strata
```

```
  stratum   arr ci_lower ci_upper
1       1 0.904    0.760    1.076
2       2 0.822    0.696    0.975
3       3 0.798    0.666    0.961
4       4 0.716    0.587    0.881
5       5 0.589    0.463    0.761
```

Subsequently, we define a function `weights.strata.function()` to calculate the weights for each stratum. The weight is the proportion of treated patients in each stratum over all treated patients in the sample:

```r
weights.strata.function <- function(data, stratum) {
  n_DMT1_stratum <- nrow(data %>% filter(ps.strata == stratum & treatment == "DMT1"))
  n_DMT1_all <- nrow(data %>% filter(treatment == "DMT1"))
  weight <- n_DMT1_stratum/n_DMT1_all
  return(c("stratum" = stratum, "weight" = weight))
}

weights.strata <- as.data.frame(t(sapply(1:5, weights.strata.function, data = dat)))
weights.strata
```

```
  stratum    weight
1       1 0.1429870
2       2 0.1815584
3       3 0.2076623
4       4 0.2244156
5       5 0.2433766
```

```r
# Create table with ARRs and weights for each PS stratum
arr.weights.merged <- merge(arr.strata, weights.strata, by = "stratum")

# Calculate the weighted ARR for each stratum
arr.weights.merged <- arr.weights.merged %>%
  mutate(weighted.arr = as.numeric(arr) * weight)

# Sum the weighted ARRs across strata to get the overall ATT
sum(arr.weights.merged$weighted.arr)
```

```
[1] 0.7482462
```

We now define a new function `ps.stratification.bootstrap()` that integrates estimation of the ATT and the PS weights for bootstrapping purposes:

```
ps.stratification.bootstrap <- function(data, inds) {
  d <- data[inds,]

  d$ps.strata <- cut(d$ps,
                     breaks = c(quantile(dat$ps, probs = seq(0, 1, by = 0.2))),
                     labels = seq(5),
                     include.lowest = TRUE)

  arr.strata <- as.data.frame(t(sapply(1:5, att.strata.function,
                                       data = d, confint = FALSE)))

  weights.strata <- as.data.frame(t(sapply(1:5, weights.strata.function, data = d)))

  return(arr.strata$arr[1] * weights.strata$weight[1] +
           arr.strata$arr[2] * weights.strata$weight[2] +
           arr.strata$arr[3] * weights.strata$weight[3] +
           arr.strata$arr[4] * weights.strata$weight[4] +
           arr.strata$arr[5] * weights.strata$weight[5])
}
```

We can now estimate the treatment effect and its confidence interval using the bootstrap procedure:

```
library(boot)
```

```
Attaching package: 'boot'

The following object is masked from 'package:survival':

    aml
```

```
set.seed(1854)
arr.stratification.boot <- boot(data = dat,
                                statistic = ps.stratification.bootstrap,
                                R = 1000)

# Bootstrapped ARR
```

```r
median(arr.stratification.boot$t)
```

```
[1] 0.7558609
```

```r
# Bootstrapped ARR 95% CI
quantile(arr.stratification.boot$t[,1], c(0.025, 0.975))
```

```
     2.5%     97.5%
0.6835885 0.8362947
```

3.5 Propensity score weighting

3.5.1 Calculate propensity score weights for ATT

Propensity score weighting reweights the study sample to generate an artificial population (i.e., pseudo-population) in which the covariates are no longer associated with treatment, thereby removing confounding by measured covariates. For the ATT, the weight for all treated patients is set to one. Conversely, the weight for patients in the control group is set to the propensity score divided by one minus the propensity score, that is, (PS/(1 − PS)). We estimated stabilized weights to address extreme weights.

```r
library(WeightIt)

w.out <- weightit(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                  data = dat,
                  method = "ps",
                  estimand = "ATT")
                  #stabilize = TRUE)

w.out
```

```
A weightit object
 - method: "ps" (propensity score weighting)
 - number of obs.: 10000
 - sampling weights: none
 - treatment: 2-category
 - estimand: ATT (focal: DMT1)
 - covariates: age, female, prevDMTefficacy, prerelapse_num
```

```
summary(w.out)
```

```
                Summary of weights

- Weight ranges:

              DMT0 DMT1
Unadjusted 2300.   7700
Adjusted   1043.16 7700
```

3.5.3 Estimate the ATT

One way to estimate the ATT is to use the survey package. The function `svyglm()` generates model-robust (Horvitz-Thompson-type) standard errors by default, and thus does not require additional adjustments.

```r
library(survey)

weighted.data <- svydesign(ids = ~1, data = dat, weights = ~w.out$weights)

weighted.fit <- svyglm(y ~ treatment + offset(log(years)),
                       family = poisson(link = "log"),
                       design = weighted.data)

exp(coef(weighted.fit)["treatmentDMT1"])
```

```
treatmentDMT1
    0.7083381
```

```r
exp(confint(weighted.fit))["treatmentDMT1",]
```

```
    2.5 %    97.5 %
0.6245507 0.8033662
```

As indicated above, propensity score weighting yielded an ATT estimate of 0.71 (95% CI: 0.66; 0.76).

An alternative approach is to use `glm()` to estimate the treatment effect and calculate robust standard errors.

```
# Alternative way to estimate treatment effect
weighted.fit2 <- glm(y ~ treatment + offset(log(years)),
               family = poisson(link = "log"),
               data = dat,
               weights = w.out$weights)

# Extract the estimated ARR
exp(coef(weighted.fit2))["treatmentDMT1"]
```

```
treatmentDMT1
    0.7083381
```

```
# Calculate robust standard error and p-value of the log ARR
coeftest(weighted.fit2, vcov. = vcovHC)["treatmentDMT1",]
```

```
     Estimate    Std. Error       z value      Pr(>|z|)
-3.448337e-01  6.442745e-02 -5.352280e+00  8.685284e-08
```

```
# Derive 95% confidence interval of the ARR
exp(lmtest::coefci(weighted.fit2,
       level = 0.95, # 95% confidence interval
       vcov. = vcovHC)["treatmentDMT1",])
```

```
    2.5 %    97.5 %
0.6243094 0.8036767
```

Using this approach, the ATT estimate was 0.71 (95% CI: 0.62; 0.8).

3.6 Regression adjustment for the propensity score for the ATE

In this approach, a regression model is fitted to describe the observed outcome as a function of the received treatment and the estimated propensity score:

```r
ps.reg.fit <- glm(y ~ treatment + ps + offset(log(years)),
                  family = poisson(link = "log"),
                  data = dat)

summary(ps.reg.fit)
```

```
Call:
glm(formula = y ~ treatment + ps + offset(log(years)), family = poisson(link = "log"),
    data = dat)

Deviance Residuals:
    Min       1Q   Median       3Q      Max
-2.0160  -0.7336  -0.4441  -0.1352   4.2634

Coefficients:
             Estimate Std. Error z value Pr(>|z|)

(Dispersion parameter for poisson family taken to be 1)

    Null deviance: 7514.7  on 9999  degrees of freedom
Residual deviance: 7443.0  on 9997  degrees of freedom
AIC: 12378

Number of Fisher Scoring iterations: 6
```

```r
# ATE
exp(coef(ps.reg.fit))["treatmentDMT1"]
```

```
treatmentDMT1
    0.7741606

Waiting for profiling to be done...
Waiting for profiling to be done...
```

Bootstrapped confidence intervals can be obtained as follows:

```
# Function to bootstrap for 95% CIs
ps.reg.bootstrap <- function(data, inds) {
  d <- data[inds,]

  fit <- glm(y ~ treatment + ps + offset(log(years)),
             family = poisson(link = "log"),
             data = d)

  return(exp(coef(fit))["treatmentDMT1"])
}

set.seed(1854)

# Generate 1000 bootstrap replicates

4 Effect Modification Analysis within the Propensity score Framework

Mohammad Ehsanul Karim (University of British Columbia)

Observational comparative effectiveness studies often adopt propensity score analysis to adjust for confounding. Although this approach is relatively straightforward to implement, careful thought is needed when treatment effect heterogeneity is present. This chapter illustrates the estimation of subgroup-specific treatment effects using (traditional) covariate adjustment methods, propensity score matching, propensity score weighting, propensity score stratification, and covariate adjustment using propensity scores.

First, we need to install the R package `simcausal`, which can be obtained from GitHub:

```
devtools::install_github('osofr/simcausal', build_vignettes = FALSE)
```

We will use the following data-generation model:

```
require(simcausal)
D <- DAG.empty()
D <- D +
  node("age", distr = "rnorm",
       mean = 2, sd = 4) +
  node("gender", distr = "rbern",
       prob = plogis(4)) +
  node("education", distr = "rbern",
       prob = plogis(3 + 5 * age)) +
  node("diet", distr = "rbern",
       prob = plogis(1 - 3 * education)) +
  node("income", distr = "rbern",
       prob = plogis(2 - 5 * education - 4 * age)) +
  node("smoking", distr = "rbern",
       prob = plogis(1 + 1.2 * gender + 2 * age)) +
  node("hypertension", distr = "rbern",
```

```
        prob = plogis(1 + log(3) * diet +
                        log(1.3) * age +
                        log(3.5) * smoking +
                        log(0.5) * gender))
Dset <- set.DAG(D)
```

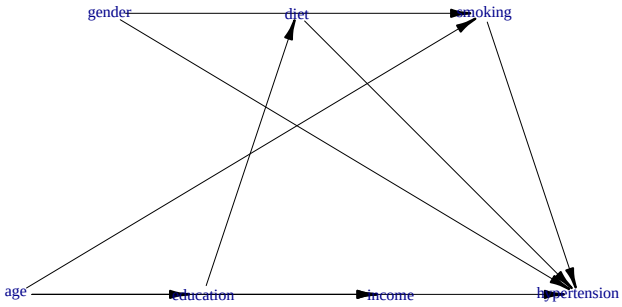
Below is the diagram, with pink lines representing open backdoor path.

```
using the following vertex attributes:
```

```
NAdarkbluenone100.50
```

```
using the following edge attributes:
```

```
black0.210.60.5
```



We can now generate an example dataset:

```
Obs.Data <- sim(DAG = Dset, n = 50000, rndseed = 123)
Obs.Data$smoking <- as.character(Obs.Data$smoking)
Obs.Data$income <- as.factor(Obs.Data$income)
Obs.Data$income <- relevel(Obs.Data$income, ref = "1")
```

Sample data from the hypothetical example of association between hypertension and smoking, where other variables such as income, age [centered], gender, education and diet also plays a role in the data generation process.

	age	gender	education	diet	income	smoking	hypertension
34901	12.29	1	1	1	0	1	1
149	10.40	1	1	0	0	1	1
10060	2.99	1	1	0	0	1	0
22220	-4.31	0	0	0	1	0	1
9979	-6.44	0	0	0	1	0	1

4.1 Covariate adjustment

4.1.1 Interaction approach

Below, we estimate a logistic regression model to assess whether the effect of smoking (the exposure) on hypertension is modified by income levels. This model considers the following variables:

- Outcome: `hypertension`
- Exposure variables: `smoking` and `income`
- Confounders: `age` and `gender`

```
require(jtools)

fit.w.em <- glm(hypertension ~ smoking * income + age + gender,
            family = binomial(link = "logit"), data = Obs.Data)

results.model <- summ(fit.w.em, exp = TRUE)
```

	exp(Est.)	2.5%	97.5%	z val.	p
(Intercept)	5.46	4.37	6.82	14.97	0.00
smoking1	2.93	2.60	3.30	17.69	0.00
income0	0.48	0.41	0.57	-8.28	0.00
age	1.29	1.27	1.31	36.77	0.00
gender	0.54	0.43	0.67	-5.55	0.00
smoking1:income0	1.27	1.04	1.56	2.33	0.02

Results indicate that the interaction between smoking status and income level is statistically significant ($p = 0.02$).

If we expand previous model to adjust for an additional confounder `education`, we have:

```r
fit.w.int <- glm(hypertension ~ smoking * income + age + gender + education,
                 family = binomial(link = "logit"),
                 data = Obs.Data)

results.int.model <- summ(fit.w.int, exp = TRUE)
```

	exp(Est.)	2.5%	97.5%	z val.	p
(Intercept)	5.69	4.56	7.11	15.31	0.00
smoking1	3.35	2.95	3.79	18.85	0.00
income0	1.09	0.85	1.40	0.68	0.49
age	1.30	1.28	1.32	37.32	0.00
gender	0.54	0.43	0.67	-5.58	0.00
education	0.42	0.35	0.51	-8.87	0.00
smoking1:income0	1.10	0.90	1.35	0.93	0.35

The interaction term between income and smoking is no longer statistically significant (p = 0.35).

We can generate a summary report from aforementioned effect modification analysis.

```r
require(interactionR)

em.object <- interactionR(fit.w.em,
                          exposure_names = c("income0", "smoking1"),
                          ci.type = "mover", ci.level = 0.95,
                          em = TRUE, recode = FALSE)
```

The table below depicts the adjusted odds ratios for income levels (`high = 0`, and `low = 1`). The variables `CI.ll` and `CI.ul` depict the lower and upper limits of the 95 percent confidence intervals, `OR11` $= OR_{A=1,M=1}$, `OR10` $= OR_{A=1}$, `OR01` $= OR_{M=1}$ and `OR00` captures the reference.

Similarly, for the analysis adjusting for an additional confounder `education`, we have:

```r
# test run with additive model
Obs.Data$smoking <- as.numeric(as.character(Obs.Data$smoking))
Obs.Data$income <- as.numeric(as.character(Obs.Data$income))
fit.w.int.add <- glm(hypertension ~ smoking * income + age + gender + education,
                     family = gaussian(link = "identity"), data = Obs.Data)
sim_slopes(fit.w.int.add, pred = smoking, modx = income,
           exp = TRUE, robust = TRUE,
```

Table 4.1: Summary report from an interaction analysis when investigating association between two exposure variables (smoking and income) and hypertension.

Measures	Estimates	CI.ll	CI.ul
OR00	1.00	NA	NA
OR01	2.93	2.60	3.30
OR10	0.48	0.41	0.57
OR11	1.80	1.63	1.98
OR(smoking1 on outcome [income0==0]	2.93	2.60	3.30
OR(smoking1 on outcome [income0==1]	3.72	3.14	4.41
Multiplicative scale	1.27	1.04	1.56
RERI	-0.61	-0.98	-0.29

Table 4.2: Summary report from an interaction analysis when investigating association between two exposure variables (smoking and income) and hypertension.

Measures	Estimates	CI.ll	CI.ul
OR00	1.00	NA	NA
OR01	1.09	0.85	1.40
OR10	3.35	2.95	3.79
OR11	4.02	3.29	4.92
OR(income0 on outcome [smoking1==0]	1.09	0.85	1.40
OR(income0 on outcome [smoking1==1]	1.20	1.00	1.45
OR(smoking1 on outcome [income0==0]	3.35	2.95	3.79
OR(smoking1 on outcome [income0==1]	3.69	3.11	4.37
Multiplicative scale	1.10	0.90	1.35
RERI	0.59	0.03	1.27
AP	0.15	0.00	0.26
SI	1.24	1.01	1.53

```
    confint = TRUE, data = Obs.Dat)
```

```
JOHNSON-NEYMAN INTERVAL

When income is INSIDE the interval [-3.27, 16.87], the slope of smoking is
p < .05.

Note: The range of observed values of income is [0.00, 1.00]
```

```
SIMPLE SLOPES ANALYSIS

Slope of smoking when income = 0.00 (0):

  Est.   S.E.   2.5%   97.5%   t val.      p
------ ------ ------ ------- -------- ------
  0.25   0.02   1.24    1.34    12.76   0.00

Slope of smoking when income = 1.00 (1):

  Est.   S.E.   2.5%   97.5%   t val.      p
------ ------ ------ ------- -------- ------
  0.28   0.01   1.30    1.34    34.53   0.00
```

4.1.2 Stratification

This approach involves estimating a regression model in different strata of the discrete effect modifier `income`:

```
# Estimate the prognostic effect of smoking in low income individuals
fit.income1 <- glm(hypertension ~ smoking + age + gender,
            family = binomial(link = "logit"),
            data = subset(Obs.Data, income == 1))

# Estimate the prognostic effect of smoking in high income individuals
fit.income0 <- glm(hypertension ~ smoking + age + gender,
            family = binomial(link = "logit"),
            data = subset(Obs.Data, income == 0))
```

The table below summarizes the adjusted odds ratios for smoking across the different income levels (`low = 1`, and `high = 0`) as obtained using the stratified approach.

Value of income	Estimate	2.5 %	97.5 %	z value	p value
1	3.07	2.71	3.47	17.65	0
0	3.59	3.02	4.26	14.57	0

Note that we can obtain the same results by estimating a regression model with an interaction term between the modifier and all covariates:

```
fit.all.int <- glm(hypertension ~ income * (smoking + age + gender),
                   family = binomial(link = "logit"), data = Obs.Data)
```

```r
# Odds ratio for smoking in individuals with low income
exp(coef(fit.all.int)["smoking"])
```

```
smoking
3.59026
```

```r
# Odds ratio for smoking in individuals with high income
exp(coef(fit.all.int)["smoking"] + coef(fit.all.int)["income:smoking"])
```

```
 smoking
3.066878
```

4.2 Propensity score matching

4.2.1 Stratification with exact matching within subgroups

We simulate another example dataset using aforementioned DAG, but restrict the sample size to 5000 individuals to reduce computational burden.

```r
set.seed(123)
Obs.Data <- sim(DAG = Dset, n = 5000, rndseed = 123)
```

We first estimate the propensity of smoking in the high-income group (`income == 0`):

```r
require(MatchIt)

match.income.0 <- matchit(smoking ~ age + gender,
                          data = subset(Obs.Data, income == 0),
                          method = "full", distance = "glm", link = "logit")
data.income.0 <- match.data(match.income.0)
```

Below, we draw a sample from the high-income group based on the hypothetical example of an association between hypertension and smoking. Here age [centered], gender, education, and diet are covariates.

```
            age gender education diet income smoking hypertension  distance
657   6.0810120      0         1    1      0       1            1 0.9999874
4932  1.6109860      1         1    0      0       1            0 0.9943155
```

```
252  -0.2475055      1         1    1      0       0            1 0.8525107
2693 -0.2511048      1         1    0      0       1            1 0.8516785
1646 -0.2836155      1         0    1      0       1            1 0.8439843
        weights subclass
657  1.00000000       36
4932 1.00000000       50
252  0.03296089       25
2693 1.00000000       25
1646 1.00000000        4
```

Now, we do the same for the low-income group (`income == 1`):

```
match.income.1 <- matchit(smoking ~ age + gender,
                          data = subset(Obs.Data, income == 1),
                          method = "full", distance = "glm", link = "logit")
data.income.1 <- match.data(match.income.1)
```

We estimated the exposure effect from a weighted outcome model for the matched data. While the `weights` are essential for estimating the point estimate from the outcome model, the `subclass` variable assists in calculating the robust variance of the exposure effect estimate.

```
# Treatment effect estimation
fit.income.0 <- glm(hypertension ~ smoking + age + gender,
                    data = data.income.0, weights = weights,
                    family = binomial("logit"))
fit.income.1 <- glm(hypertension ~ smoking + age + gender,
                    data = data.income.1, weights = weights,
                    family = binomial("logit"))
# Robust variance calculation
fit.nexp.adj.res1 <- summ(fit.income.1,
                          robust = TRUE,
                          cluster = "subclass",
                          confint = TRUE)
fit.nexp.adj.res0 <- summ(fit.income.0,
                          robust = TRUE,
                          cluster = "subclass",
                          confint = TRUE)
```

4.2.2 Joint approach without exact matching within subgroups

Here, entire cohort data is used to estimate the propensity scores, and the effect modifier `income` is considered as a covariate in the propensity score model:

Table 4.3: Subgroup-specific treatment effect estimates (expressed in log-OR) from the hypothetical example using the stratified approach.

Value of income	Est.	2.5%	97.5%	z val.	p
0	3.74	-37.58	45.06	0.18	0.86
1	1.39	0.94	1.85	6.04	0.00

```
ps.formula <- as.formula("smoking ~ age + gender + income")
match.obj.j <- matchit(ps.formula, data = Obs.Data,
                       method = "full",
                       distance = "glm",
                       link = "logit")
match.data.j <- match.data(match.obj.j)
```

```
fit.joint.no.exact <- glm(hypertension ~ smoking*income + age + gender,
                          data = match.data.j,
                          weights = weights,
                          family = binomial("logit"))
require(interactions)
nem.nexp.adj.res <- sim_slopes(fit.joint.no.exact,
                               pred = smoking,
                               modx = income,
                               robust = "HC1",
                               cluster = "subclass",
                               johnson_neyman = TRUE,
                               confint = TRUE,
                               data = match.data.j)
```

Table 4.4: Subgroup-specific treatment effect estimates (expressed in log-OR) from the hypothetical example using the joint approach.

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	3.85	1.00	1.89	5.82	3.84	0
1	1.40	0.28	0.85	1.95	4.99	0

4.2.3 Joint approach with exact matching within subgroups

We specify the moderator variable's name in the `exact` argument of the `matchit` function.

```
ps.formula.no.mod <- as.formula("smoking ~ age + gender")
match.obj.js <- matchit(ps.formula.no.mod, data = Obs.Data,
                        method = "full", distance = "glm",link = "logit",
                        exact = "income")
match.data.js <- match.data(match.obj.js)
fit.joint.exact <- glm(hypertension ~ smoking*income + age + gender,
                       data = match.data.js, weights = weights,
                       family = binomial("logit"))
js.nexp.adj.res <- sim_slopes(fit.joint.exact,
                              pred = smoking, modx = income,
                              robust = "HC1", cluster = "subclass",
                              johnson_neyman = FALSE, confint = TRUE,
                              data = match.data.js)
```

Table 4.5: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the Joint model, separate matching approach.

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	3.89	1.01	1.92	5.87	3.87	0
1	1.38	0.28	0.84	1.93	4.95	0

4.2.4 Interaction approach without exact matching within subgroups

Analysts incorporate relevant moderator-covariate interactions into the propensity score model that align with biological plausibility. For instance, in the case study we considered an interaction between age (a covariate) and income (a moderator), but did not include other interactions terms.

```
ps.formula.with.int <- formula("smoking ~ age*income + gender")
match.obj.i <- matchit(ps.formula.with.int, data = Obs.Data,
                       method = "full", distance = "glm",link = "logit")
match.data.i <- match.data(match.obj.i)
fit.int.no.exact <- glm(hypertension ~ smoking*income + age + gender,
                        data = match.data.i, weights = weights,
                        family = binomial("logit"))
i.nexp.adj.res <- sim_slopes(fit.int.no.exact,
                             pred = smoking, modx = income,
                             robust = "HC1", cluster = "subclass",
                             johnson_neyman = FALSE, confint = TRUE,
                             data = match.data.i)
```

Table 4.6: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the interaction approach.

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	3.87	1.00	1.90	5.83	3.86	0
1	1.39	0.28	0.84	1.94	4.95	0

4.2.5 Interaction approach with exact matching within subgroups

This method bears resemblance to the interaction approach for propensity score estimation. However, when it comes to matching, researchers match within each moderator subgroup.

```
match.obj.is <- matchit(ps.formula.with.int, data = Obs.Data,
                        method = "full", distance = "glm",link = "logit",
                        exact = "income")
match.data.is <- match.data(match.obj.is)
fit.int.exact <- glm(hypertension ~ smoking*income + age + gender,
                     data = match.data.is, weights = weights,
                     family = binomial("logit"))
is.nexp.adj.res <- sim_slopes(fit.int.exact,
                              pred = smoking, modx = income,
                              robust = "HC1", cluster = "subclass",
                              johnson_neyman = FALSE, confint = TRUE,
                              data = match.data.is)
```

Table 4.7: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the interaction model, separate matching approach.

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	3.86	1.00	1.90	5.83	3.85	0
1	1.40	0.28	0.85	1.95	4.99	0

4.3 Propensity Score Weighting

4.3.1 Common model

This approach adds confounder-moderator interactions in the common weight model.

```
require(WeightIt)
W.out <- weightit(ps.formula.with.int,
                  data = Obs.Data,
                  method = "ps",
                  estimand = "ATT")
require(survey)
d.w <- svydesign(~1, weights = W.out$weights, data = Obs.Data)
fit2w <- svyglm(hypertension ~ smoking*income, design = d.w,
                family = binomial("logit"))
w.nexp.adj.res <- sim_slopes(fit2w, pred = smoking, modx = income,
                             confint = TRUE)
```

Table 4.8: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the weighting approach.

Value of income	Est.	S.E.	2.5%	97.5%	t val.	p
0	2.66	0.63	1.42	3.89	4.23	0
1	1.32	0.25	0.83	1.82	5.24	0

We can adjust previous analysis model to adopt stabilized weights for the propensity score (`stabilize = TRUE`):

```
W.out.st <- weightit(ps.formula.with.int, data = Obs.Data,
                     method = "ps",
                     estimand = "ATT",
                     stabilize = TRUE)
d.sw <- svydesign(~1, weights = W.out.st$weights, data = Obs.Data)
fit2sw <- svyglm(hypertension ~ smoking*income + age + gender,
                 design = d.sw,
                 family = binomial("logit"))
ws.nexp.adj.res <- sim_slopes(fit2sw,
                              pred = smoking, modx = income,
                              confint = TRUE)
```

Table 4.9: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using stabilized propensity score weights.

Value of income	Est.	S.E.	2.5%	97.5%	t val.	p
0	2.27	0.73	0.84	3.69	3.12	0
1	1.32	0.25	0.83	1.82	5.23	0

4.3.2 Separate models

Propensity score weighting approach with weights estimated separately from each subgroup:

```
ps.formula.with.no.int <- formula("smoking ~ age + gender")
W.out1 <- weightit(ps.formula.with.no.int,
                   data = subset(Obs.Data, income == 1),
                   method = "ps",
                   estimand = "ATT")
trimmed.weight.1.percent1 <- trim(W.out1$weights,
                                  at = 1, lower = TRUE)
```

Table 4.10: Weight summaries before and after truncation.

Weight	Min.	1st Qu.	Median	Mean	3rd Qu.	Max.
Raw weights	0	0.01	0.11	0.45	1	11.69
1% truncated weights	0	0.01	0.11	0.44	1	7.61

```
# Outcome model for income = 1
d.w1 <- svydesign(~1, weights = trimmed.weight.1.percent1,
                  data = subset(Obs.Data, income == 1))
fit2unadj1 <- svyglm(hypertension ~ smoking, design = d.w1,
                     family = binomial("logit"))

# weight model for income = 0
W.out0 <- weightit(ps.formula, data = subset(Obs.Data, income == 0),
                   method = "ps", estimand = "ATT")
trimmed.weight.1.percent0 <- trim(W.out0$weights, at = 1, lower = TRUE)

# Outcome model for income = 0
d.w0 <- svydesign(~1, weights = trimmed.weight.1.percent0,
                  data = subset(Obs.Data, income == 0))
fit2unadj0 <- svyglm(hypertension ~ smoking, design = d.w0,
                     family = binomial("logit"))

fit.exp.adj.res1 <- summ(fit2unadj1, confint = TRUE)
fit.exp.adj.res0 <- summ(fit2unadj0, confint = TRUE)
```

Table 4.11: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the propensity score weighting approach (Separate weight models).

Value of income	Est.	2.5%	97.5%	t val.	p
0	2.21	1.27	3.15	4.60	0
1	1.34	0.85	1.83	5.36	0

4.3.3 Weights from the subgroup balancing propensity scores

Subgroup balancing propensity scores for propensity score weighting:

```
w.out <- weightit(smoking ~ age + gender + income,
                  data = Obs.Data,
                  method = "ps", estimand = "ATT")
w.out.sb <- sbps(w.out, moderator = "income")
d.w.sb <- svydesign(~1, weights = w.out.sb$weights, data = Obs.Data)
fit2unadj.sb <- svyglm(hypertension ~ smoking*income, design = d.w.sb,
                       family = binomial("logit"))
sb.w.nexp.adj.res <- sim_slopes(fit2unadj.sb,
                                pred = smoking,
                                modx = income,
                                confint = TRUE,
                                johnson_neyman = FALSE,)
```

Table 4.12: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using the subgroup balancing weighting approach.

Value of income	Est.	S.E.	2.5%	97.5%	t val.	p
0	2.68	0.64	1.44	3.92	4.22	0
1	1.32	0.25	0.82	1.82	5.22	0

4.4 Covariate adjustment for the propensity score

4.4.1 As continuous covariate

An implementation of propensity scores as a continuous covariate in the outcome model:

```r
# Separate models for each subgroup

# For subgroup income = 1
Obs.Data$ps[Obs.Data$income == 1] <- glm(ps.formula,
                                         data = subset(Obs.Data, income == 1),
                                         family = "binomial")$fitted.values
fit2adj1 <- glm(hypertension ~ smoking + age + gender,
                family = binomial("logit"),
                data = subset(Obs.Data, income == 1))

# For subgroup income = 0
Obs.Data$ps[Obs.Data$income == 0] <- glm(ps.formula,
                                         data = subset(Obs.Data, income == 0),
                                         family = "binomial")$fitted.values
fit2adj0 <- glm(hypertension ~ smoking + age + gender,
                family = binomial("logit"),
                data = subset(Obs.Data, income == 0))

fit.nexp.adj.res1 <- summ(fit2adj1, robust = TRUE, confint = TRUE)
fit.nexp.adj.res0 <- summ(fit2adj0, robust = TRUE, confint = TRUE)
```

Table 4.13: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using Propensity Score as a covariate adjustment approach (considering separate models for each subgroup).

Value of income	Est.	2.5%	97.5%	z val.	p
0	1.16	0.56	1.75	3.83	0
1	1.37	0.96	1.77	6.61	0

```r
# Common model
Obs.Data$ps <- glm(ps.formula.with.int, data = Obs.Data,
                   family = "binomial")$fitted.values
```

```
Warning: glm.fit: fitted probabilities numerically 0 or 1 occurred
```

```r
fit2adjc <- glm(hypertension ~ smoking*income + age + gender + ps,
                family = binomial("logit"),
                data = Obs.Data)
c.nexp.adj.res <- sim_slopes(fit2adjc,
```

```
                                pred = smoking, modx = income,
                                confint = TRUE,
                                data = Obs.Data)
```

Table 4.14: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using Propensity Score as a covariate adjustment approach (considering a common model).

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	1.17	0.29	0.61	1.74	4.07	0
1	1.43	0.23	0.98	1.87	6.30	0

4.4.2 As quantiles

The propensity scores as a categorical covariate, broken by quintiles, in the outcome model.

```
Obs.Data$ps <- glm(ps.formula.with.int,
                   data = Obs.Data,
                   family = "binomial")$fitted.values
quintiles <- quantile(Obs.Data$ps,
                      prob = seq(from = 0, to = 1, by = 0.2),
                      na.rm = T)
Obs.Data$psq <- cut(Obs.Data$ps, breaks = quintiles,
                    labels = seq(1,5), include.lowest = T)
Obs.Data$psq <- as.factor(Obs.Data$psq)

fit2adjq <- glm(hypertension ~ (smoking*psq)*income,
                family = binomial("logit"),
                data = Obs.Data)
cq.nexp.adj.res <- sim_slopes(fit2adjq,
                              pred = smoking,
                              modx = income,
                              confint = TRUE,
                              data = Obs.Data)
```

4.5 Propensity Score Stratification

Here is an implementation of propensity score stratification approach by using the marginal mean weighting through stratification (MMWS):

Table 4.15: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using Propensity Score as a covariate adjustment approach (as quintiles).

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	3.08	0.63	1.85	4.32	4.91	0
1	2.60	0.47	1.68	3.51	5.56	0

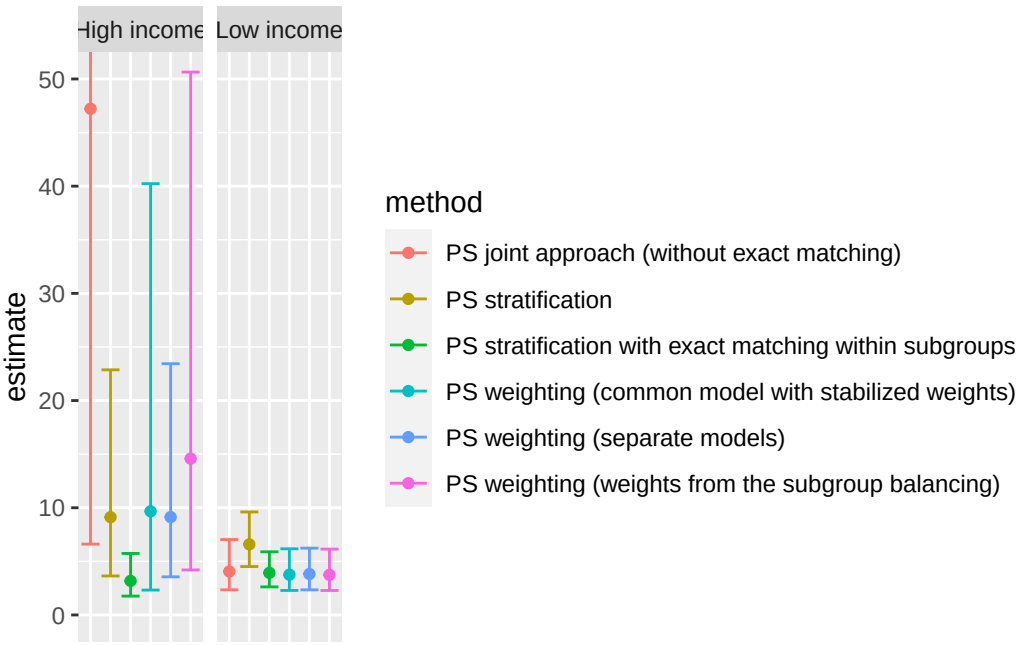
```
match.obj <- matchit(ps.formula, data = Obs.Data,
                     method = "subclass", subclass = 3,
                     estimand = "ATT", min.n = 10)
data.subclass <- match.data(match.obj)
subclass.fit <- glm(hypertension ~ smoking*income, family = binomial("logit"),
               data = data.subclass,
               weights = weights)
subclass.nexp.adj.res <- sim_slopes(subclass.fit,
                                    pred = smoking,
                                    modx = income,
                                    confint = TRUE,
                                    robust = "HC3",
                                    johnson_neyman = FALSE,
                                    data = data.subclass)
```

Table 4.16: Subgroup-specific exposure effect estimates (expressed in log-OR) from the hypothetical example using propensity score stratification approach.

Value of income	Est.	S.E.	2.5%	97.5%	z val.	p
0	2.21	0.47	1.29	3.13	4.71	0
1	1.89	0.19	1.51	2.26	9.78	0

4.6 Summary

The marginal odds ratios for `smoking` are summarized below



Version info

This chapter was rendered using the following version of R and its packages:

5 Dealing with missing data

Johanna Munoz (Julius Center for Health Sciences and Primary Care)
Thomas Debray (Smart Data Analysis and Statistics B.V.)

In this example, we consider the estimation of comparative treatment effects in the absence of treatment-effect heterogeneity.

5.0.1 Prepare R environment

```
library(mice)
library(dplyr)
library(ggmice)
library(MatchThem)

# Load relevant chapter functions
source("resources/chapter 09/functions.r")
```

5.0.2 Generating an observational dataset

We can simulate an observational dataset of $N = 3000$ patients as follows:

```
data_noHTE <- generate_data(n = 3000, seed = 1234)
```

This dataset does not (yet) contain any missing values;

The simulated dataset contains two treatment groups with differences in baseline characteristics. For example, the figure below shows that we have baseline imbalance in age.

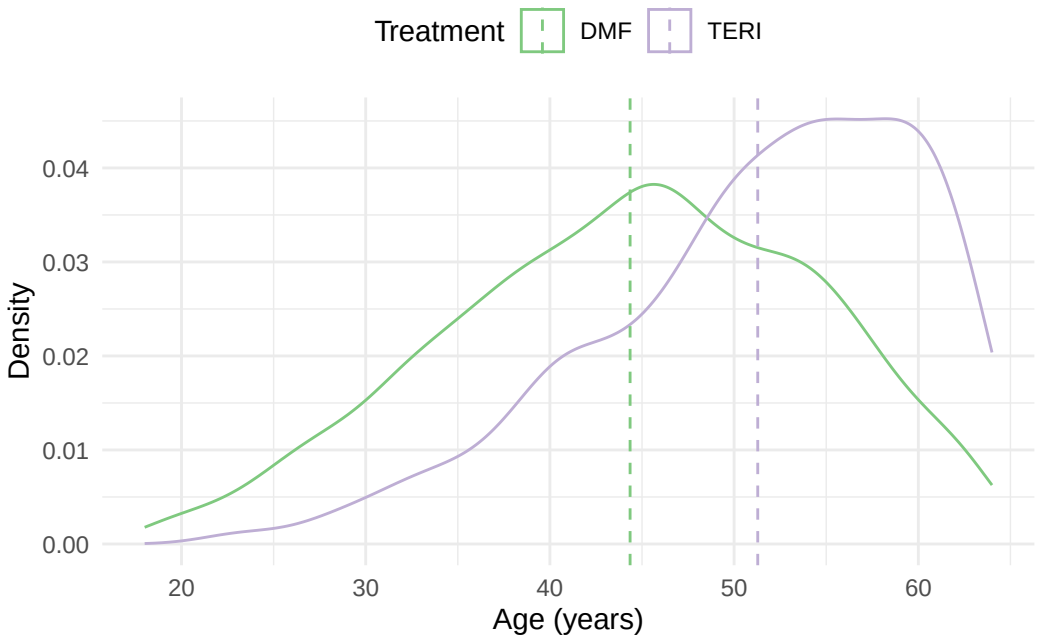

Figure 5.1: Distribution of the EDSS score at each time point

5.0.3 Generating missing values

Missing values can be generated using the function `getmissdata()`, which considers the following patterns of missingness for the previous number of relapses (`prerelapse_num`):

1. MAR: missingness depends on `age` and `sex`
2. MART: missingness depends on `age`, `sex` and the treatment variable `treatment`
3. MARTY: missingness depends on `age`, `sex`, `treatment` and the outcome variable `y`
4. MNAR: missingness depends on `age`, `sex` and `prerelapse_num`

```
mdata_noHTE <- getmissdata(data_noHTE, "MART")
```

After introducing missing values, we only have complete data for $N = 946$ patients.

5.1 Analysis of incomplete data

5.1.1 Complete Case Analysis

Below, we describe how to estimate the ATE using propensity score matching.

Table 5.1: Baseline characteristics of the incomplete dataset.

	DMF	TERI	Overall
	(N=2265)	(N=735)	(N=3000)
Age (years)			
Mean (SD)	44.4 (10.0)	51.3 (8.72)	46.2 (10.1)
Median [Min, Max]	45.0 [18.0, 64.0]	53.0 [23.0, 64.0]	47.0 [18.0, 64.0]
Missing	248 (10.9%)	57 (7.8%)	305 (10.2%)
Female Sex			
Yes	1740 (76.8%)	526 (71.6%)	2266 (75.5%)
No	525 (23.2%)	209 (28.4%)	734 (24.5%)
Efficacy of previous DMT			
None	740 (32.7%)	325 (44.2%)	1065 (35.5%)
Low	190 (8.4%)	59 (8.0%)	249 (8.3%)
Medium or High	830 (36.6%)	246 (33.5%)	1076 (35.9%)
Missing	505 (22.3%)	105 (14.3%)	610 (20.3%)
Prior medical costs			
Mean (SD)	9970 (10700)	25500 (35400)	13900 (21200)
Median [Min, Max]	6530 [164, 102000]	12500 [259, 337000]	7450 [164, 337000]
Missing	257 (11.3%)	52 (7.1%)	309 (10.3%)
Number of prior symptoms			
0	157 (6.9%)	58 (7.9%)	215 (7.2%)
1	1169 (51.6%)	411 (55.9%)	1580 (52.7%)
>=2	435 (19.2%)	159 (21.6%)	594 (19.8%)
Missing	504 (22.3%)	107 (14.6%)	611 (20.4%)
Number of prior relapses			
Mean (SD)	0.453 (0.671)	0.408 (0.646)	0.436 (0.662)
Median [Min, Max]	0 [0, 4.00]	0 [0, 3.00]	0 [0, 4.00]
Missing	1365 (60.3%)	152 (20.7%)	1517 (50.6%)

```r
impdata <- mdata_noHTE[complete.cases(mdata_noHTE), ]

# Apply Matching
mout <- matchit(DMF ~ age + female + prevDMTefficacy + premedicalcost + prerelapse_num,
                data = impdata,
                family = binomial,
                method = "full",
                caliper = 0.2,
                estimand = "ATE",
                replace = FALSE)

mdata <- as.data.table(match.data(mout))
match_mod <- glm("y ~ DMF" , offset = log(years),
                 family = poisson(link = "log"),
                 data = mdata,
                 weights = weights)

# Estimate robust variance-covariance matrix
tx_var <- vcovCL(match_mod, cluster = ~ subclass, sandwich = TRUE)
```

We can extract the treatment effect estimate as follows:

```r
# Treatment effect estimate (log rate ratio)
coef(match_mod)["DMF"]
```

```
      DMF
-0.3685717
```

```r
# Standard error
sqrt(tx_var["DMF", "DMF"])
```

```
[1] 0.1521243
```

5.1.2 Multiple Imputation (within method)

In this approach, we will generate $m = 5$ imputed datasets and perform matching within each imputed dataset. We first need to specify how the variables `prevDMTefficacy`, `premedicalcost`, `numSymptoms`, `prerelapse_num` and `age` will be imputed:

```r
# We add a covariate for log(years)
impdata <-  mdata_noHTE %>% mutate(logyears = log(years))

# Specify the conditional imputation models
form_y <- list(prevDMTefficacy ~ age + female + logyears + premedicalcost + numSymptoms +
                 treatment + prerelapse_num + y,
               premedicalcost ~ age + female + logyears + prevDMTefficacy + numSymptoms +
                 treatment + prerelapse_num + y,
               numSymptoms ~ age + female + premedicalcost + logyears + prevDMTefficacy +
                 prerelapse_num + treatment + y,
               prerelapse_num ~ age + female + premedicalcost + logyears + prevDMTefficacy
                 numSymptoms + treatment + y,
               age ~ prerelapse_num + female + premedicalcost + logyears + prevDMTefficacy
                 numSymptoms + treatment + y)
form_y <- name.formulas(form_y)

# Adopt predictive mean matching for imputing the incomplete variables
imp0 <- mice(impdata, form = form_y, maxit = 0)
method <- imp0$method
method["numSymptoms"] <- "pmm"
method["prevDMTefficacy"] <- "pmm"

# Generate 5 imputed datasets
imp <- mice(impdata, form = form_y, method = method, m = 5, maxit = 100)
```

We can now estimate the ATE using propensity score analysis in each of the imputed datasets. We here adopt full matching without replacement.

```r
# Matching based on PS model
mout <- matchthem(DMF ~ age + female + prevDMTefficacy + premedicalcost + prerelapse_num,
                  datasets = imp,
                  approach = "within",
                  method = "full",
                  caliper = 0.2,
                  family = binomial,
                  estimand = "ATE",
                  distance = "glm",
                  link = "logit",
                  replace = FALSE)
```

The results are then combined using Rubin's rules. We adopt robust standard errors to account for clustering of matched individuals.

```
match_mod <- summary(pool(with(mout, svyglm(y ~ DMF + offset(log(years)),
                                            family = poisson(link = "log")),
                                  cluster = TRUE)), conf.int = TRUE)
```

We can extract the treatment effect estimate and corresponding standard error as follows:

```
# Treatment effect estimate (log rate ratio)
(match_mod %>% filter(term == "DMF"))$estimate
```

```
[1] -0.1554094
```

```
# Standard error
(match_mod %>% filter(term == "DMF"))$std.error
```

```
[1] 0.2202132
```

5.1.3 Multiple Imputation (across method)

```
# Matching based on PS model
mout <- matchthem(DMF ~ age + female + prevDMTefficacy + premedicalcost + prerelapse_num,
                  datasets = imp,
                  approach = "across",
                  method = "full",
                  caliper = 0.2,
                  family = binomial,
                  estimand = "ATE",
                  distance = "glm",
                  link = "logit",
                  replace = FALSE)
```

The results are then combined using Rubin's rules. We adopt robust standard errors to account for clustering of matched individuals.

```
match_mod <- summary(pool(with(mout, svyglm(y ~ DMF, offset = log(years),
                                            family = poisson(link = "log")),
                                  cluster = TRUE)), conf.int = TRUE)
```

We can extract the treatment effect estimate and corresponding standard error as follows:

```r
# Treatment effect estimate (log rate ratio)
(match_mod %>% filter(term == "DMF"))$estimate
```

```
[1] -0.3461563
```

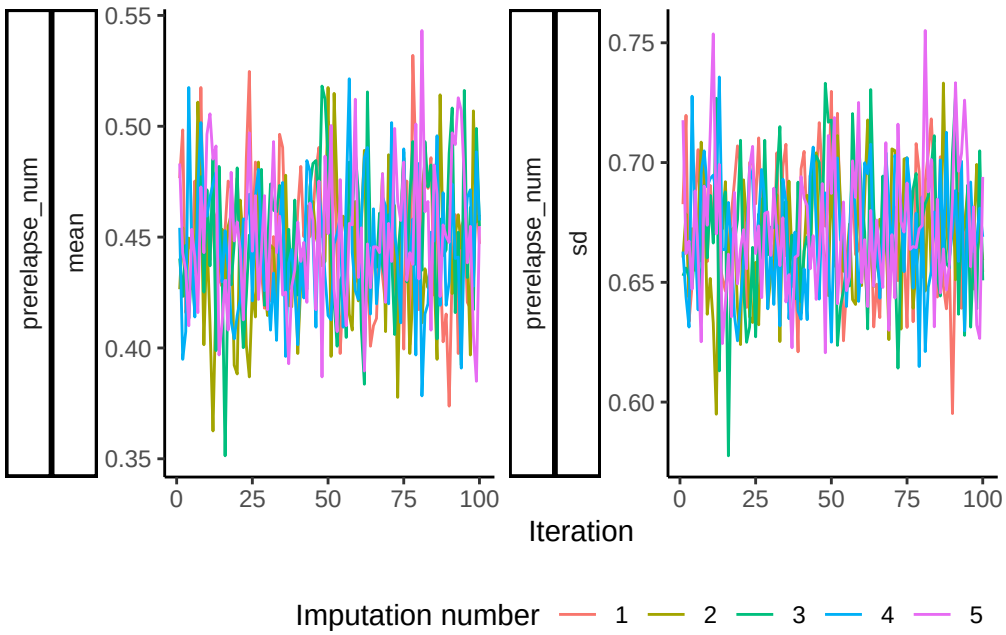
```r
# Standard error
(match_mod %>% filter(term == "DMF"))$std.error
```

```
[1] 0.1351187
```

5.2 Convergence checking

We can inspect convergence for the imputed variable `prerelapse_num` using a trace plot:

```r
plot_trace(imp, vrb = "prerelapse_num")
```



5.3 Results

Analysis methods:

- **Full Data**: The treatment effect is estimated in the original data of $N = 3000$ patients where no missing values are present. This estimate can be used as a benchmark to compare the missing data methods.
- **Complete Case Analysis**: The treatment effect is estimated using all data from $N = 946$ patients that do not have any missing values.
- **Missing Indicator**: The treatment effect is estimated in the incomplete dataset of $N = 3000$ patients. The propensity score model includes a missing indicator variable for each incomplete covariate.
- **MICE (within method)**: A treatment effect is estimated within each imputed dataset using propensity score analysis. Using Rubin's rule, the five treatment effects are combined into a single treatment effect.
- **MICE (ITE method)**: The missing covariates and potential outcomes are imputed simultaneously. Treatment effect estimates are derived by taking the average of the individualized treatment effect estimates Y|DMF - Y|TERI.

6 Systematic review and meta-analysis of Real-World Evidence

Dimitris Mavridis (University of Ioannina)
Thomas Debray (Smart Data Analysis and Statistics B.V.)

We first load the required packages

```
library(dplyr)
library(gemtc)
library(netmeta)
```

6.1 Pairwise meta-analysis of clinical trials

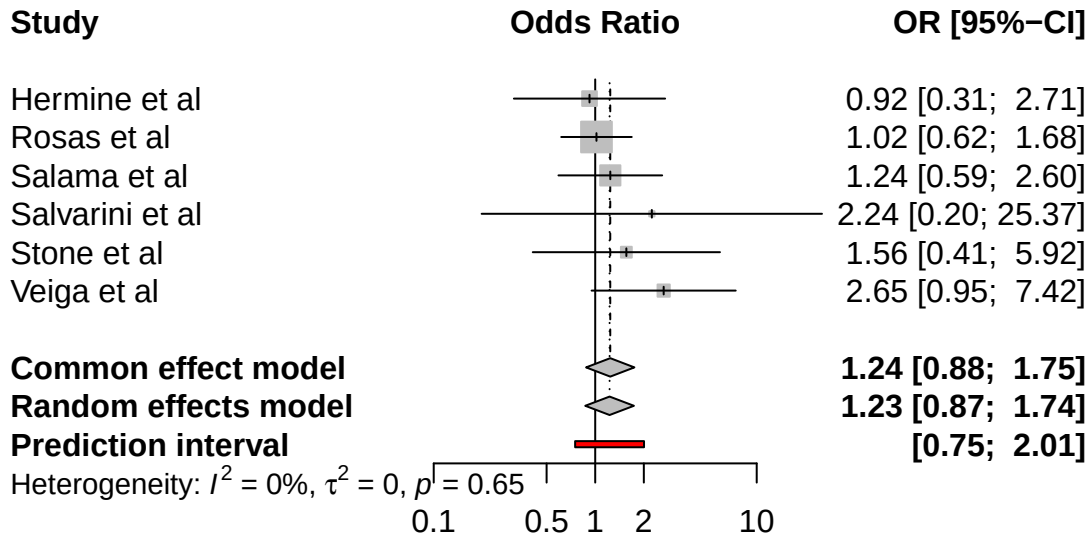
6.1.1 Toculizumab for coronavirus disease 2019

In this example, we consider the results from a systematic literature review of clinical trials investigating any pharmacological in hosptialized patients with coronavirus disease 2019 (Selvarajan et al. 2022). A total of 23 randomized controlled trials were included and studied seven different interventions: dexamethasone, remdesivir, tocilizumab, hydroxychloroquine, combination of lopinavir/ritonavir, favipiravir and interferon- . We here focus on the synthesis of 7 trials that comparted toculizumab (`TOCI`) to standard care (`STD`) and collected mortality data.

studlab	treat1	treat2	event1	n1	event2	n2
Hermine et al	TOCI	STD	7	63	8	67
Rosas et al	TOCI	STD	58	294	28	144
Salama et al	TOCI	STD	26	249	11	128
Salvarini et al	TOCI	STD	2	60	1	66
Stone et al	TOCI	STD	9	161	3	82
Veiga et al	TOCI	STD	14	65	6	64

We now conduct a pairwise meta-analysis to assess the pooled effect of tocilizumab versus standard care. For each study, the log odds ratio and corresponding standard error is derived after which the corresponding estimates are pooled using the Mantel-Haenszel method.

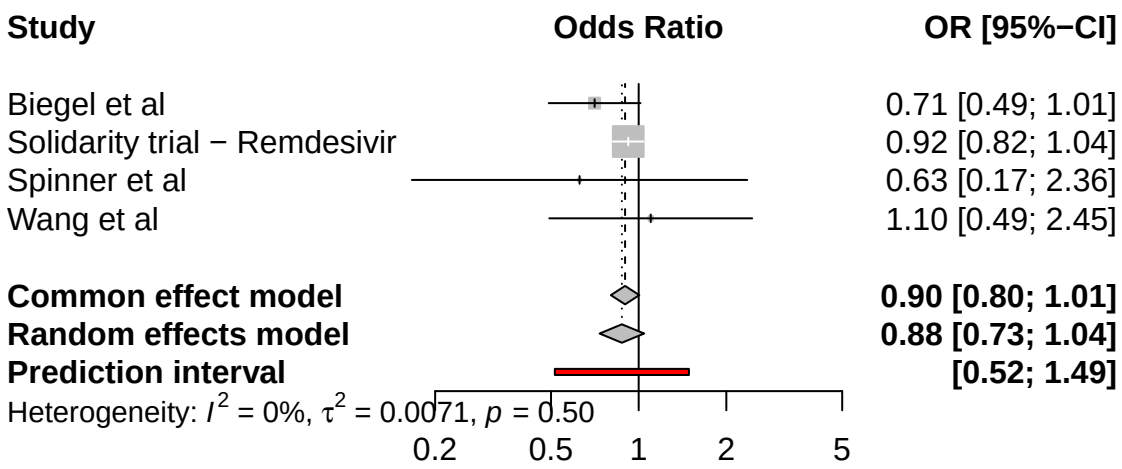
```
results.TOCI <- metabin(event1,n1,event2,n2,studlab,data=tocilizumab,
                        sm="OR",main="tocilizumab vs standard care",
                        prediction=TRUE)
forest(results.TOCI, leftcols = "studlab", rightcols = "effect.ci")
```



Altough a random effects meta-analysis was conducted, no heterogeneity was found (τ=0, with a 95% confidence interval ranging from 0 to 0.85).

6.1.2 Remdesivir for coronavirus disease 2019

In aforementioned example, a total of 4 trials compared remdesivir to standard care:



6.2 Network meta-analysis of clinical trials

We here use the R packages `netmeta` for conducting a frequentist network meta-analysis. A detailed tutorial on the use of `netmeta` is available from the book Doing Meta-Analysis with R: A Hands-On Guide.

6.2.1 Interventions for coronavirus disease 2019

We here consider data from a study which aimed to assess the comparative effectiveness of remdesivir and tocilizumab for reducing mortality in hospitalised COVID-19 patients. 80 trials were identified from two published network meta-analyses (Selvarajan et al. 2022), (Siemieniuk et al. 2020), a living COVID-19 trial database (COVID-NMA Initiative) [Covid-NMA.com], and a clinical trial database [clinicaltrials.gov]. Trials were included in this study if the patient population included hospitalized COVID-19 patients, active treatment was remdesivir or tocilizumab, comparator treatment was placebo or standard care, short-term mortality data was available, and the trial was published. 21 trials were included. For included trials, a risk of bias score was extracted from the COVID-NMA Initiative.

Below, we conduct a random effects network meta-analysis where we consider standard care (STD) as the control treatment. Note that we have one study where zero cell counts occur, this study will not contribute to the NMA as the log odds ratio and its standard error cannot be determined.

```
NMA.covid <- netmeta(TE = TE, seTE = seTE, treat1 = treat1, treat2 = treat2,
                     studlab = studlab, data = covid, sm = "OR", ref = "STD",
                     comb.random = TRUE, common = FALSE, warn = FALSE)
NMA.covid
```

```
Number of studies: k = 20
Number of pairwise comparisons: m = 20
Number of treatments: n = 3
Number of designs: d = 2

Random effects model

Treatment estimate (sm = 'OR', comparison: other treatments vs 'STD'):
         OR           95%-CI     z p-value
REM  0.8999 [0.8067; 1.0039] -1.89  0.0588
STD       .                .     .       .
TOCI 0.8301 [0.7434; 0.9268] -3.31  0.0009

Quantifying heterogeneity / inconsistency:
tau^2 = 0; tau = 0; I^2 = 0% [0.0%; 48.9%]

Tests of heterogeneity (within designs) and inconsistency (between designs):
                   Q d.f. p-value
Total          16.38   18  0.5663
Within designs 16.38   18  0.5663
Between designs  0.00    0      --
```

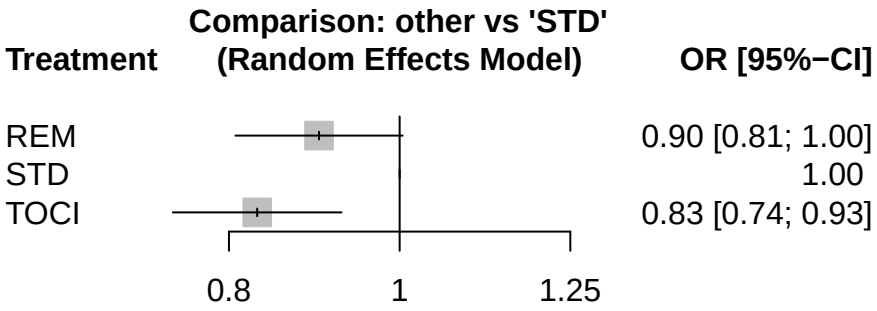
A league table of the treatment effect estimates is given below:

```
netleague(NMA.covid)
```

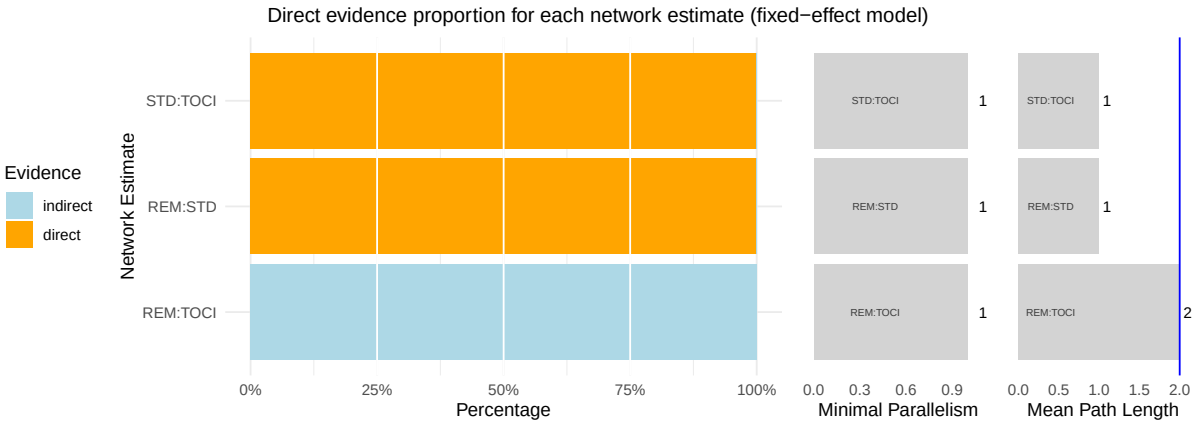
```
League table (random effects model):

                    REM 0.8999 [0.8067; 1.0039]                       .
 0.8999 [0.8067; 1.0039]                     STD 1.2047 [1.0789; 1.3451]
 1.0842 [0.9282; 1.2663] 1.2047 [1.0789; 1.3451]                    TOCI
```

We can also present the results in a forest plot:



The figure below shows the percentage of direct and indirect evidence used for each estimated comparison.



We now consider a Bayesian random effects network meta-analysis that analyzes the observed event counts using a binomial link function.

```
bdata <- data.frame(study = studlab,
                    treatment = treat,
                    responders = event,
                    sampleSize = n)

network <- mtc.network(data.ab  = bdata)

model <- mtc.model(network,
                   likelihood = "binom",
                   link = "log",
                   linearModel = "random",
                   n.chain = 3)
```

```r
# Adaptation
mcmc1 <- mtc.run(model, n.adapt = 1000, n.iter = 1000, thin = 10)
```

```

Quantifying heterogeneity / inconsistency:
tau^2 = 0.0004; tau = 0.0205; I^2 = 0.6% [0.0%; 42.3%]

Tests of heterogeneity (within designs) and inconsistency (between designs):
                   Q d.f. p-value
Total          27.18   27  0.4543
Within designs 27.18   27  0.4543
Between designs 0.00    0      --
```

We can calculate the P score for each treatment as follows:

```
netrank(NMA.covidf)
```

```
     P-score
TOCI  0.9070
DEXA  0.8357
REM   0.7143
STD   0.4027
LOPI  0.3899
HCQ   0.1336
INTB  0.1166
```

6.2.2 Pharmacologic treatments for chronic obstructive pulmonary disease

In this example, we consider the resuls from a systematic review of randomized controlled trials on pharmacologic treatments for chronic obstructive pulmonary disease (Baker, Baker,

and Coleman 2009). The primary outcome, occurrence of one or more episodes of COPD exacerbation, is binary (yes / no). For this outcome, five drug treatments (fluticasone, budesonide, salmeterol, formoterol, tiotropium) and two combinations (fluticasone + salmeterol, budesonide + formoterol) were compared to placebo. The authors considered the two combinations as separate treatments instead of evaluating the individual components.

```
data(Baker2009)
```

study	year	id	treatment	exac	total
Llewellyn-Jones 1996	1996	1	Fluticasone	0	8
Llewellyn-Jones 1996	1996	1	Placebo	3	8
Boyd 1997	1997	2	Salmeterol	47	229
Boyd 1997	1997	2	Placebo	59	227
Paggiaro 1998	1998	3	Fluticasone	45	142
Paggiaro 1998	1998	3	Placebo	51	139

```
Baker <- pairwise(treat = treatment,
                  event = exac,
                  n = total,
                  studlab = id,
                  sm = "OR",
                  data = Baker2009)

NMA.COPD <- netmeta(TE = TE, seTE = seTE, treat1 = treat1, treat2 = treat2,
                    studlab = studlab, data = Baker, sm="OR", ref = "Placebo",
                    comb.random = TRUE)
```

```
Warning: Comparisons with missing TE / seTE or zero seTE not considered in
network meta-analysis.

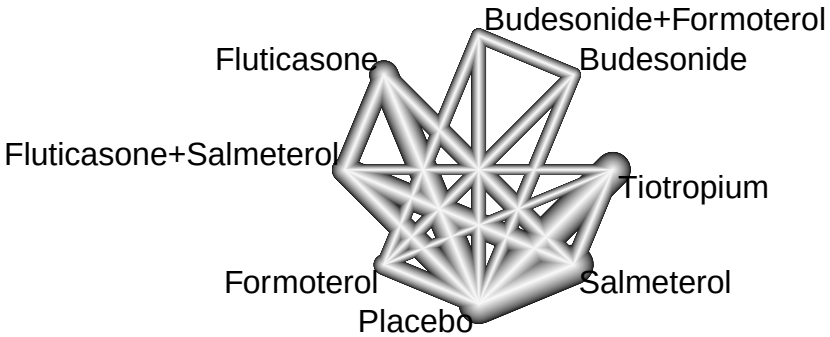
      39 Fluticasone+Salmeterol    Placebo NA   NA
      39 Fluticasone+Salmeterol Salmeterol NA   NA
      39              Salmeterol    Placebo NA   NA
```

```
netgraph(NMA.COPD)
```



6.2.3 Advanced Therapies for Ulcerative Colitis

In this example, we consider a systematic literature review of Phase 3 randomized controlled trials investigating the following advanced therapies: infliximab, adalimumab, vedolizumab, golimumab, tofacitinib, ustekinumab, filgotinib, ozanimod, and upadacitinib (Panaccione et al. 2023). This review included 48 RCTs, from which 23 were found eligible for inclusion in a network meta-analysis. The included RCT populations were largely comparable in their baseline characteristics, though some heterogeneity was noted in weight, disease duration, extent of disease, and concomitant medications. A risk of bias assessment showed a low risk of bias for all included RCTs, which were all industry sponsored.

We here focus on the synthesis of 18 trials that contributed efficacy data for induction in bio-naive populations. The following FDA- and/or EMA-approved biologic or SMD doses were investigated:

- Adalimumab subcutaneous 160 mg at week 0, 80 mg at week 2, and 40 mg at week 4 (`ADA160/80`)
- Infliximab intravenous 5 mg/kg (`INF5`) at weeks 0, 2, and 6 then every 8 weeks
- Infliximab intravenous 10 mg/kg (`INF10`) at weeks 0, 2, and 6 then every 8 weeks
- Filgotinib oral 100 mg once daily (`FIL100`)
- Filgotinib oral 200 mg once daily (`FIL200`)
- Golimumab subcutaneous 200 mg at week 0 and 100 mg at week 2 (`GOL200/100`)
- Ozanimod oral 0.23 mg once daily for 4 days, 0.46 mg once daily for 3 days, then 0.92 mg once daily (`OZA0.92`)
- Tofacitinib oral 10 mg twice daily for 8 weeks (`TOF10`)
- Upadacitinib oral 45 mg once daily for 8 weeks (`UPA45`)
- Ustekinumab intravenous 6 mg/kg at week 0 (`UST6`)
- Vedolizumab intravenous 300 mg at weeks 0, 2, and 6 (`VED300`)

The reference treatment is placebo (`PBO`).

Table 6.4: Efficacy outcomes (i.e., clinical remission) data of induction bio-naïve populations

studlab	treat1	treat2	event1	n1	event2	n2
ACT-1	INF10	INF5	39	122	47	121
ACT-1	INF10	PBO	39	122	18	121

SELECTION	FIL100	FIL200	47	277	60	245
SELECTION	FIL100	PBO	47	277	17	137
SELECTION	FIL200	PBO	60	245	17	137
TRUE NORTH	OZA0.92	PBO	66	299	10	151
U-ACCOMPLISH	UPA45	PBO	54	166	3	81
U-ACHIEVE Study 2	UPA45	PBO	41	145	4	72
ULTRA-1	ADA160/80	PBO	24	130	12	130
ULTRA-2	ADA160/80	PBO	32	150	16	145
UNIFI	UST6	PBO	27	147	15	151

The corresponding network is displayed below:

Below, we conduct a random effects network meta-analysis of the reported study effects (expressed as odds ratio) and consider placebo (`treat = "PBO"`) as the control treatment.

```
NMA.uc <- netmeta(TE = TE, seTE = seTE, treat1 = treat1, treat2 = treat2,
                  studlab = studlab, data = UlcerativeColitis, sm = "OR",
                  ref = "PBO", common = FALSE, comb.random = TRUE)
NMA.uc
```

All treatments except `FIL100` and `UST6` are significantly more efficacious than `PBO` at inducing clinical remission. We can now estimate the probabilities of each treatment being at each possible rank and the SUCRAs (Surface Under the Cumulative RAnking curve):

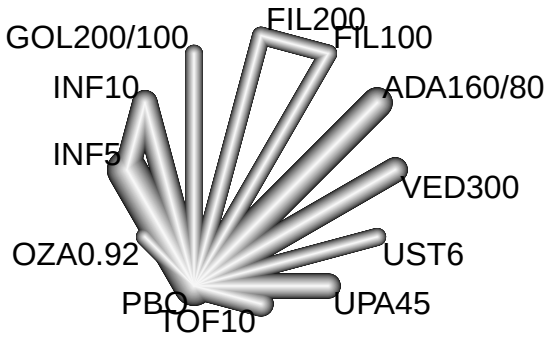

Figure 6.3: Evidence network of 18 trials that contributed efficacy data for induction in bio-naive populations

```r
sucra.uc <- rankogram(NMA.uc, nsim = 100, random = TRUE, common = FALSE,
                      small.values = "undesirable")

# Exctract the SUCRA values
sucra.uc$ranking.random
```

```
 ADA160/80     FIL100     FIL200 GOL200/100      INF10       INF5    OZA0.92
0.26909091 0.20363636 0.42181818 0.63000000 0.60090909 0.75727273 0.74000000
       PBO      TOF10      UPA45       UST6     VED300
0.01636364 0.37454545 0.98454545 0.37181818 0.63000000
```

These results indicate that 98.5% of the evaluated treatments are worse than `UPA45`.

7 Dealing with irregular and informative visits

Janie Coulombe (Université de Montréal)
Thomas Debray (Smart Data Analysis and Statistics B.V.)

We first load the required packages

```
library(dplyr)
library(broom)
library(ggplot2)
library(mice)
```

Subsequently, we load the relevant R scripts:

```
source("resources/chapter12_sim.r")
source("resources/chapter12_fig_functions.r")
source("resources/chapter12_mlmi.r")
```

7.1 Example dataset

Below, we generate an example dataset that contains information on the treatment allocation `x` and three baseline covariates `age`, `sex` and `edss` (EDSS at treatment start). The discrete outcome `y` represents the Expanded Disability Status Scale (EDSS) score after `time` months of treatment exposure. Briefly, the EDSS is a semi-continuous measure that varies from 0 (no disability) to 10 (death).

```
set.seed(9843626)

dataset  <- sim_data_EDSS(npatients = 500,
                          ncenters = 10,
                          follow_up = 12*5, # Total follow-up (number of months)
                          sd_a_t = 0.5,   # DGM - Within-visit variation in EDSS scores
```

```
baseline_EDSS = 1.3295,    # DGM - Mean baseline EDDS score
sd_alpha_ij = 1.46,    # DGM - Between-subject variation in base
sd_beta1_j = 0.20,    # DGM - Between-site variation in baseline
mean_age = 42.41,
sd_age = 10.53,
min_age = 18,
beta_age = 0.05, # DGM - prognostic effect of age
beta_t = 0.014,  # DGM - prognostic effect of time
beta_t2 = 0,    # DGM - prognostic effect of time squared
delta_xt = 0, # DGM - interaction treatment time
delta_xt2 = 0, # 0.0005    # DGM - interaction treatment time2
p_female = 0.75,
beta_female = -0.2 ,  ## DGM - prognostic effect of male sex
delta_xf = 0,      ## DGM - interaction sex treatment
rho = 0.8,             # DGM - autocorrelation of between alpha_
corFUN = corAR1,       # DGM - correlation structure of the late
tx_alloc_FUN = treatment_alloc_confounding_v2 ) ## or treatment_
```

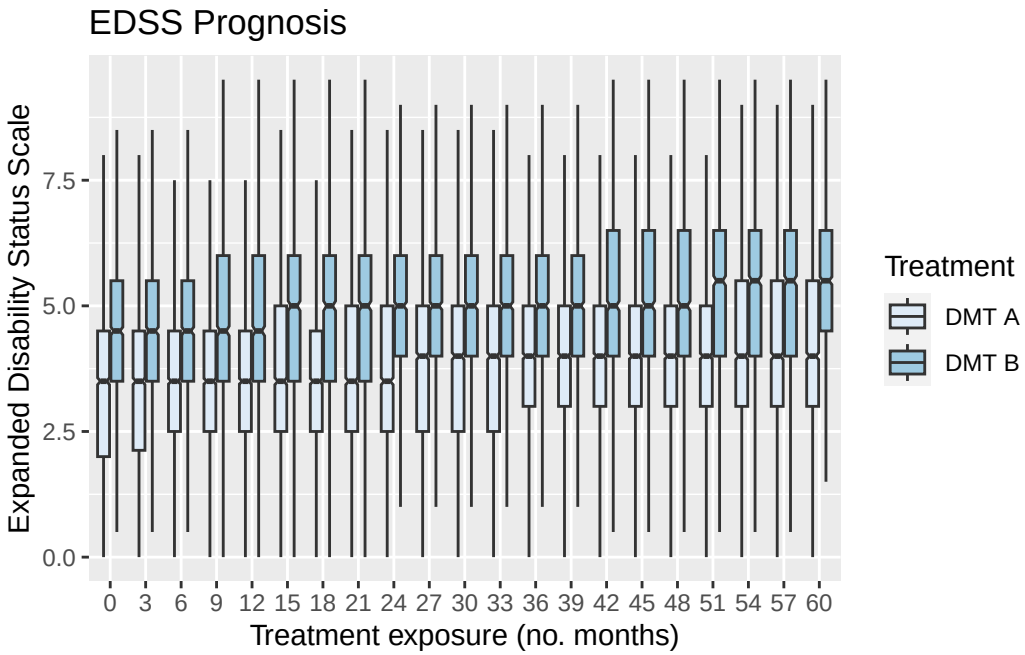

Figure 7.1: Distribution of the EDSS score at each time point

We remove the outcome y according to the informative visit process that depends on the received treatment, gender, and age.

```r
dataset_visit <- censor_visits_a5(dataset, seed = 12345) %>%
  dplyr::select(-y) %>%
  mutate(time_x = time*x)
```

In the censored data, a total of 17 out of 5000 patients have a visit at `time=60`.

7.2 Estimation of treatment effect

We will estimate the marginal treatment effect at time `time=60`.

7.2.1 Original data

```r
origdat60 <- dataset %>% filter(time == 60)

# Predict probability of treatment allocation
fitps <- glm(x ~ age + sex + edss, family = 'binomial',
             data = origdat60)

# Derive the propensity score
origdat60 <- origdat60 %>% mutate(ipt = ifelse(x == 1, 1/predict(fitps, type = 'response')
                                               1/(1-predict(fitps, type = 'response'))))

# Estimate
fit_ref_m <- tidy(lm(y ~ x, weight = ipt, data = origdat60), conf.int = TRUE)
```

7.2.2 Doubly-weighted marginal treatment effect

```r
obsdat60 <- dataset_visit %>% mutate(visit = ifelse(is.na(y_obs),0,1)) %>% filter(time ==

gamma <- glm(visit ~ x + sex + age + edss, family = 'binomial', data = obsdat60)$coef

obsdat60 <- obsdat60 %>% mutate(rho_i = 1/exp(gamma["(Intercept)"] +
                                                gamma["x"]*x +
                                                gamma["sex"]*sex +
                                                gamma["age"]*age))

# Predict probability of treatment allocation
```

```r
fitps <- glm(x ~ age + sex + edss, family='binomial', data = obsdat60)

# Derive the propensity score
obsdat60 <- obsdat60 %>% mutate(ipt = ifelse(x==1, 1/predict(fitps, type='response'),
                                             1/(1-predict(fitps, type='response'))))

fit_w <- tidy(lm(y_obs ~ x, weights = ipt*rho_i, data = obsdat60), conf.int = TRUE)
```

7.2.3 Multilevel multiple imputation

We adopt the imputation approach proposed by Debray et al. (2023). Briefly, we impute the entire vector of `y_obs` for all 61 potential visits and generate 10 imputed datasets. Note: `mlmi` currently does not support imputation of treatment-covariate interaction terms.

```r
imp <- impute_y_mice_3l(dataset_visit, seed = 12345)
```

We can now estimate the treatment effect in each imputed dataset

```r
# Predict probability of treatment allocation
fitps <- glm(x ~ age + sex + edss, family='binomial', data = dataset_visit)

# Derive the propensity score
dataset_visit <- dataset_visit %>% mutate(ipt = ifelse(x==1, 1/predict(fitps, type='respon
                                                       1/(1-predict(fitps, type='response'

Q <- U <- rep(NA, 10) # Error variances

for (i in seq(10)) {
  dati <- cbind(dataset_visit[,c("x","ipt","time")], y_imp = imp[,i]) %>% filter(time == 6

  # Estimate
  fit <- tidy(lm(y_imp ~ x, weight = ipt, data = dati), conf.int = TRUE)

  Q[i] <- fit %>% filter(term == "x") %>% pull(estimate)
  U[i] <- (fit %>% filter(term == "x") %>% pull(std.error))**2
}

fit_mlmi <- pool.scalar(Q = Q, U = U)
```

7.3 Reproduce the results using all data to compute the marginal effect with IIV-weighted

7.3.1 Doubly -weighted marginal treatment effect total

```
obsdatall <- dataset_visit %>% mutate(visit = ifelse(is.na(y_obs),0,1))
gamma <- glm(visit ~ x + sex + age + edss, family = 'binomial', data = obsdatall)$coef
obsdatall <- obsdatall %>% mutate(rho_i = 1/exp(gamma["(Intercept)"] +
                                                gamma["x"]*x +
                                                gamma["sex"]*sex +
                                                gamma["age"]*age))
# Predict probability of treatment allocation
fitps <- glm(x ~ age + sex + edss, family='binomial', data = obsdatall)
# Derive the propensity score
obsdatall <- obsdatall %>% mutate(ipt = ifelse(x==1, 1/predict(fitps, type='response'),
                                               1/(1-predict(fitps, type='response'))))
fit_w <- tidy(lm(y_obs ~ x, weights = ipt*rho_i, data = obsdatall), conf.int = TRUE)
```

8 Prediction of individual treatment effect using data from multiple studies

Orestis Efthimiou (Institute of Social and Preventive Medicine (ISPM))

In this chapter, we discuss statistical methods for developing models to predict patient-level treatment effects using data from multiple randomized and non-randomized studies. We will first present prediction models that assume a constant treatment effect and discuss how to address heterogeneity in baseline risk. Subsequently, we will discuss approaches that allow for treatment effect modification by adopting two different approaches in an IPD-MA context, namely the risk modelling and the effect modelling approach. For both approaches, we will first discuss how to combine IPD from RCTs comparing the same two treatments. We will then discuss how these methods can be extended to include randomized data from multiple treatments, real-world data, and published aggregate data. We will discuss statistical software to implement these approaches and provide example code as supporting information. Real examples will be used throughout to illustrate the main methods.

We hereby provide code for estimating patient-level treatment effects for the case when we have patient-level data from multiple randomized trials.

8.0.1 Example of a continuous outcome

8.0.1.1 Setup

We start by simulating an artificial dataset using the R package **bipd**:

```
library(bipd)
ds <- generate_ipdma_example(type = "continuous")
```

Let us have a look at the dataset:

```
head(ds)
```

Table 8.1: The simulated dataset with a continuous outcome

	0	1	Overall
	(N=297)	(N=303)	(N=600)
z1			
Mean (SD)	0.110 (0.989)	-0.0318 (0.982)	0.0385 (0.987)
Median [Min, Max]	0.178 [-2.80, 3.17]	0.0181 [-2.92, 3.51]	0.0710 [-2.92, 3.51]
z2			
Mean (SD)	-0.00189 (1.03)	0.0334 (1.02)	0.0160 (1.03)
Median [Min, Max]	-0.000497 [-3.65, 3.44]	0.0693 [-2.88, 2.80]	0.0179 [-3.65, 3.44]
studyid			
1	50 (16.8%)	50 (16.5%)	100 (16.7%)
2	54 (18.2%)	46 (15.2%)	100 (16.7%)
3	51 (17.2%)	49 (16.2%)	100 (16.7%)
4	47 (15.8%)	53 (17.5%)	100 (16.7%)
5	50 (16.8%)	50 (16.5%)	100 (16.7%)
6	45 (15.2%)	55 (18.2%)	100 (16.7%)

```
  studyid treat         z1          z2  y
1       1     0  0.2592475 -0.44120967 11
2       1     1 -1.3611784 -0.09873159  7
3       1     1 -1.8714329 -0.40712780  7
4       1     0  1.2539349 -0.49569062 11
5       1     0  0.2053958  2.73092051 11
6       1     1 -1.2108389 -1.55772718  5
```

The simulated dataset contains information on the following variables:

- the trial indicator `studyid`
- the treatment indicator `treat`, which takes the values 0 for control and 1 for active treatment
- two prognostic variables `z1` and `z2`
- the continuous outcome `y`

8.0.1.2 Model fitting

We synthesize the evidence using a Bayesian random effects meta-analysis model. The model is given in Equation 16.7 of the book. First we need set up the data and create the model:

```
ipd <- with(ds, ipdma.model.onestage(y = y, study = studyid, treat = treat,
                                     X = cbind(z1, z2),
                                     response = "normal",
                                     shrinkage = "none"),
                                     type="random")
```

The JAGS model can be accessed as follows:

```
ipd$model.JAGS
```

```
function ()
{
    for (i in 1:Np) {
        y[i] ~ dnorm(mu[i], sigma)
        mu[i] <- alpha[studyid[i]] + inprod(beta[], X[i, ]) +
            (1 - equals(treat[i], 1)) * inprod(gamma[], X[i,
                ]) + d[studyid[i], treat[i]]
    }
    sigma ~ dgamma(0.001, 0.001)
    for (j in 1:Nstudies) {
        d[j, 1] <- 0
        d[j, 2] ~ dnorm(delta[2], tau)
    }
    sd ~ dnorm(0, 1)
    T(0, )
    tau <- pow(sd, -2)
    delta[1] <- 0
    delta[2] ~ dnorm(0, 0.001)
    for (j in 1:Nstudies) {
        alpha[j] ~ dnorm(0, 0.001)
    }
    for (k in 1:Ncovariate) {
        beta[k] ~ dnorm(0, 0.001)
    }
    for (k in 1:Ncovariate) {
        gamma[k] ~ dnorm(0, 0.001)
    }
}
<environment: 0x1350c2630>
```

We can fit the treatment effect model as follows:

```
samples <- ipd.run(ipd, n.chains = 2, n.iter = 20,
                   pars.save = c("alpha", "beta", "delta", "sd", "gamma"))
```

```

8.0.1.3 Prection

We can now predict the individualized treatment effect for a new patient with covariate values `z1=1` and `z2=0.5`.

```r
round(treatment.effect(ipd, samples, newpatient = c(z1 = 1, z2 = 0.5)), 2)
```

```
0.025   0.5 0.975
-5.12 -3.30 -2.17
```

We can also predict treatment benefit for all patients in the sample, and look at the distribution of predicted benefit.

```r
library(dplyr)
library(ggplot2)

ds <- ds %>% mutate(benefit = NA)

for (i in seq(nrow(ds))) {
  newpat <- as.matrix(ds[i, c("z1", "z2")])
  ds$benefit[i] <- treatment.effect(ipd, samples, newpatient = newpat)["0.5"]
}
```

```
ggplot(ds, aes(x = benefit)) + geom_histogram() + facet_wrap(~studyid) +
  xlab("Predicted treatment benefit")
```

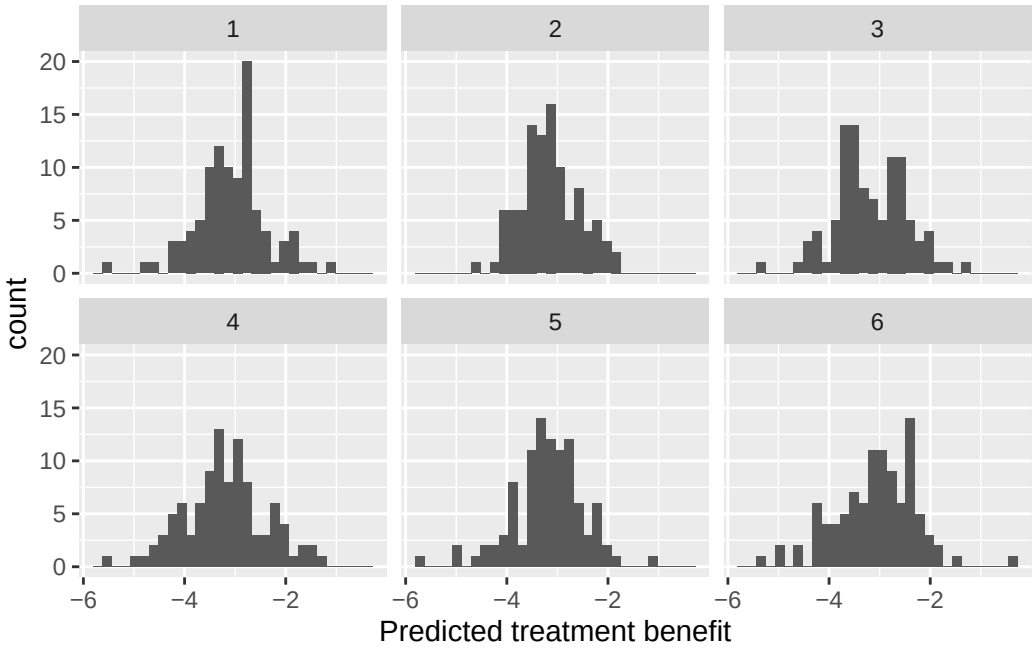

Figure 8.1: Distribution of predicted treatment benefit in each trial

8.0.1.4 Penalization

Let us repeat the analysis, but this time while penalizing the treatment-covariate coefficients using a Bayesian LASSO prior.

```
ipd <- with(ds, ipdma.model.onestage(y = y, study = studyid,
                                     treat = treat,
                                     X = cbind(z1, z2),
                                     response = "normal",
                                     shrinkage = "laplace"),
            type = "random")

samples <- ipd.run(ipd, n.chains = 2, n.iter = 20,
                   pars.save = c("alpha", "beta", "delta", "sd", "gamma"))
```

```

8.0.2 Example of a binary outcome

8.0.2.1 Setup

We now present the case of a binary outcome. We first generate a dataset as before, using the **bipd** package.

```r
ds2 <- generate_ipdma_example(type = "binary")
head(ds2)
```

```
  studyid treat          w1         w2 y
1       1     1  1.35089887 -0.5154147 0
2       1     1 -0.08053334 -0.8114272 0
3       1     0  0.20091913 -1.7691594 1
4       1     0  0.86672656  0.1125845 1
5       1     0  0.16449244  0.4123068 1
6       1     0  0.48438052  0.6447895 0
```

The simulated dataset contains information on the following variables:

- the trial indicator `studyid`
- the treatment indicator `treat`, which takes the values 0 for control and 1 for active treatment
- two prognostic variables `w1` and `w2`
- the binary outcome `y`

Table 8.2: The simulated dataset with a binary outcome

	0	1	Overall
	(N=290)	(N=310)	(N=600)
w1			
Mean (SD)	-0.0434 (0.950)	-0.0512 (1.04)	-0.0475 (0.998)
Median [Min, Max]	-0.0676 [-2.43, 2.65]	0.0229 [-2.92, 3.21]	-0.00905 [-2.92, 3.21]
w2			
Mean (SD)	0.0520 (0.996)	0.100 (0.929)	0.0768 (0.961)
Median [Min, Max]	0.0223 [-3.15, 2.35]	0.138 [-2.36, 3.07]	0.0963 [-3.15, 3.07]
studyid			
1	48 (16.6%)	52 (16.8%)	100 (16.7%)
2	49 (16.9%)	51 (16.5%)	100 (16.7%)
3	50 (17.2%)	50 (16.1%)	100 (16.7%)
4	47 (16.2%)	53 (17.1%)	100 (16.7%)
5	55 (19.0%)	45 (14.5%)	100 (16.7%)
6	41 (14.1%)	59 (19.0%)	100 (16.7%)

8.0.2.2 Model fitting

We use a Bayesian random effects model with binomial likelihood. This is similar to the model 16.7 of the book, but with a Binomial likelihood, i.e.

$$y_{ij} \sim Binomial(\pi_{ij})$$

$$logit(\pi_{ij}) == a_j + \delta_j t_{ij} + \sum_{l=1}^{L} \beta_l x_{ij} + \sum_{l=1}^{L} \gamma_l x_{ij} t_{ij}$$

The remaining of the model is as in the book. We can penalize the estimated parameters for effect modification (γ's), using a Bayesian LASSO. We can do this using again the *bipd* package:

```
ipd2 <- with(ds2, ipdma.model.onestage(y = y, study = studyid, treat = treat,
                                       X = cbind(w1, w2),
                                       response = "binomial",
                                       shrinkage = "laplace"),
             type="random", hy.prior = list("dunif", 0, 1))

ipd2$model.JAGS
```

```
function ()
{
    for (i in 1:Np) {
        y[i] ~ dbern(p[i])
        logit(p[i]) <- alpha[studyid[i]] + inprod(beta[], X[i,
            ]) + (1 - equals(treat[i], 1)) * inprod(gamma[],
            X[i, ]) + d[studyid[i], treat[i]]
    }
    for (j in 1:Nstudies) {
        d[j, 1] <- 0
        d[j, 2] ~ dnorm(delta[2], tau)
    }
    sd ~ dnorm(0, 1)
    T(0, )
    tau <- pow(sd, -2)
    delta[1] <- 0
    delta[2] ~ dnorm(0, 0.001)
    for (j in 1:Nstudies) {
        alpha[j] ~ dnorm(0, 0.001)
    }
    for (k in 1:Ncovariate) {
        beta[k] ~ dnorm(0, 0.001)
    }
    tt <- lambda
    lambda <- pow(lambda.inv, -1)
    lambda.inv ~ dunif(0, 5)

8.1 Estimating heterogeous treatment effects in network meta-analysis

8.1.1 Example of a continuous outcome

8.1.1.1 Setup

We use again the bipd package to simulate a dataset:

```r
ds3 <- generate_ipdnma_example(type = "continuous")
head(ds3)
```

```
  studyid treat          z1         z2  y
1       1     1 -0.71676754 -0.2400008 11
2       1     2 -0.09902842 -2.2132525  6
3       1     1 -0.98231113 -0.9942386 11
4       1     1 -1.12214354  0.3656618 11
5       1     1  0.27491151  1.8603612 11
6       1     1  0.46892886  1.2209345 11
```

Let us look into the data a bit in more detail:

8.1.1.2 Model fitting

We will use the model shown in Equation 16.8 in the book. In addition, we will use Bayesian LASSO to penalize the treatment-covariate interactions.

Table 8.3: The simulated dataset with a continuous outcome

	1	2	3	Overall

sd          0.07253  0.1077  0.1234  0.1389  0.1942
```

As before, we can use the `treatment.effect()` function of *bipd* to estimate relative effects for new patients.

```
treatment.effect(ipd3, samples, newpatient= c(1,2))
```

```
$`treatment 2`
    0.025       0.5     0.975
-2.484707 -2.306841 -2.180103

$`treatment 3`
     0.025        0.5      0.975
-0.7844990 -0.5845536 -0.4074984
```

This gives us the relative effects for all treatments versus the reference. To obtain relative effects between active treatments we need some more coding:

```
samples.all=data.frame(rbind(samples[[1]], samples[[2]]))
newpatient= c(1,2)
newpatient <- (newpatient - ipd3$scale_mean)/ipd3$scale_sd

median(
  samples.all$delta.2.+samples.all$gamma.2.1.*
    newpatient[1]+samples.all$gamma.2.2.*newpatient[2]
-
  (samples.all$delta.3.+samples.all$gamma.3.1.*newpatient[1]+
     samples.all$gamma.3.2.*newpatient[2])
)
```

```
[1] -1.734079
```

```
quantile(samples.all$delta.2.+samples.all$gamma.2.1.*
           newpatient[1]+samples.all$gamma.2.2.*newpatient[2]
         -(samples.all$delta.3.+samples.all$gamma.3.1.*newpatient[1]+
```

```
              samples.all$gamma.3.2.*newpatient[2])
          , probs = 0.025)
```

```
     2.5%
-1.886776
```

```
quantile(samples.all$delta.2.+samples.all$gamma.2.1.*
           newpatient[1]+samples.all$gamma.2.2.*newpatient[2]
         -(samples.all$delta.3.+samples.all$gamma.3.1.*newpatient[1]+
             samples.all$gamma.3.2.*newpatient[2])
         , probs = 0.975)
```

```
    97.5%
-1.620802
```

8.1.2 Modeling patient-level relative effects using randomized and observational evidence for a network of treatments

We will now follow Chapter 16.3.5 from the book. In this analysis we will not use penalization, and we will assume fixed effects. For an example with penalization and random effects, see part 2 of this vignettte.

8.1.2.1 Setup

We generate a very simple dataset of three studies comparing three treatments. We will assume 2 RCTs and 1 non-randomized trial:

```
ds4 <- generate_ipdnma_example(type = "continuous")
ds4 <- ds4 %>% filter(studyid %in% c(1,4,10)) %>%
  mutate(studyid = factor(studyid) %>%
           recode_factor(
             "1" = "1",
             "4" = "2",
             "10" = "3"),
         design = ifelse(studyid == "3", "nrs", "rct"))
```

The sample size is as follows:

```
          s1 s2 s3
treat A: 51 43 31
treat B: 49  0 25
treat C:  0 57 44
```

8.1.2.2 Model fitting

We will use the design-adjusted model, equation 16.9 in the book. We will fit a two-stage fixed effects meta-analysis and we will use a variance inflation factor. The code below is used to specify the analysis of each individual study. Briefly, in each study we adjust the treatment effect for the prognostic factors `z1` and `z2`, as well as their interaction with `treat`.

```
library(rjags)
```

```
Loading required package: coda
```

```
Linked to JAGS 4.3.2
```

```
Loaded modules: basemod,bugs
```

```
first.stage <- "
model{

for (i in 1:N){
    y[i] ~ dnorm(mu[i], tau)
    mu[i] <- a + inprod(b[], X[i,]) + inprod(c[,treat[i]], X[i,]) + d[treat[i]]
}
sigma ~ dunif(0, 5)
tau <- pow(sigma, -2)

a ~ dnorm(0, 0.001)

for(k in 1:Ncovariate){
    b[k] ~ dnorm(0,0.001)
}

for(k in 1:Ncovariate){
    c[k,1] <- 0
}
```

```
tauGamma <- pow(sdGamma,-1)
sdGamma ~ dunif(0, 5)

for(k in 1:Ncovariate){
    for(t in 2:Ntreat){
        c[k,t] ~ ddexp(0, tauGamma)
    }
}

d[1] <- 0
for(t in 2:Ntreat){
    d[t] ~ dnorm(0, 0.001)
}
}"
```

Subsequently, we estimate the relative treatment effects in the first (randomized) study comparing treatments A and B:

```
model1.spec <- textConnection(first.stage)
data1 <- with(ds4 %>% filter(studyid == 1),
              list(y = y,
                   N = length(y),
                   X = cbind(z1,z2),
                   treat = treat,
                   Ncovariate = 2,
                   Ntreat = 2))
jags.m <- jags.model(model1.spec, data = data1, n.chains = 2, n.adapt = 500,
                     quiet =  TRUE)
params <- c("d", "c")
samps4.1 <- coda.samples(jags.m, params, n.iter = 50)
samps.all.s1 <- data.frame(as.matrix(samps4.1))

samps.all.s1 <- samps.all.s1[, c("c.1.2.", "c.2.2.", "d.2.")]
delta.1 <- colMeans(samps.all.s1)
cov.1 <- var(samps.all.s1)
```

We repeat the analysis for the second (randomized) study comparing treatments A and C:

```
model1.spec <- textConnection(first.stage)
data2 <- with(ds4 %>% filter(studyid == 2),
              list(y = y,
```

```
                    N = length(y),
                    X = cbind(z1,z2),
                    treat = ifelse(treat == 3, 2, treat),
                    Ncovariate = 2,
                    Ntreat = 2))
jags.m <- jags.model(model1.spec, data = data2, n.chains = 2, n.adapt = 100,
                     quiet =  TRUE)
params <- c("d", "c")
samps4.2 <- coda.samples(jags.m, params, n.iter = 50)
samps.all.s2 <- data.frame(as.matrix(samps4.2))
samps.all.s2 <- samps.all.s2[, c("c.1.2.", "c.2.2.", "d.2.")]
delta.2 <- colMeans(samps.all.s2)
cov.2 <- var(samps.all.s2)
```

Finally, we analyze the third (non-randomized) study comparing treatments A, B, and C:

```
model1.spec <- textConnection(first.stage)
data3 <- with(ds4 %>% filter(studyid == 3),
              list(y = y,
                   N = length(y),
                   X = cbind(z1,z2),
                   treat = treat,
                   Ncovariate = 2,
                   Ntreat = 3))
jags.m <- jags.model(model1.spec, data = data3, n.chains = 2, n.adapt = 100,
                     quiet = TRUE)
params <- c("d", "c")
samps4.3 <- coda.samples(jags.m, params, n.iter = 50)
samps.all.s3 <- data.frame(as.matrix(samps4.3))

samps.all.s3 <- samps.all.s3[, c("c.1.2.", "c.2.2.", "d.2.", "c.1.3.",
                                 "c.2.3.", "d.3.")]
delta.3 <- colMeans(samps.all.s3)
cov.3 <- var(samps.all.s3)
```

The corresponding treatment effect estimates are depicted below:

We can now fit the second stage of the network meta-analysis. The corresponding JAGS model is specified below:

```
second.stage <-
"model{
```

Table 8.4: Treatment effect estimates.

study	B versus A	C versus A
study 1	-2.995 (SE = 0.057)	
study 2		-1.068 (SE = 0.054)
study 3	-3.011 (SE = 0.087)	-1.015 (SE = 0.072)

```
  #likelihood
  y1 ~ dmnorm(Mu1, Omega1)
  y2 ~ dmnorm(Mu2, Omega2)
  y3 ~ dmnorm(Mu3, Omega3*W)

  Omega1 <- inverse(cov.1)
  Omega2 <- inverse(cov.2)
  Omega3 <- inverse(cov.3)

  Mu1 <- c(gamma[,1], delta[2])
  Mu2 <- c(gamma[,2], delta[3])
  Mu3 <- c(gamma[,1], delta[2],gamma[,2], delta[3])

  #parameters
  for(i in 1:2){
    gamma[i,1] ~ dnorm(0, 0.001)

9 Visualization and interpretation of individualized treatment rule results

Xiaotong Jiang (Biogen)

In this tutorial, we will walk you through the code that implemented the precision medicine methods and generated the visualization results discussed in Chapter 18 of the book. This tutorial focuses more on helping you understand the code. We will not provide detailed interpretation of the results as they have been covered in the chapter already.

We first load all relevant functions for this chapter.

```
source("resources/chapter 18/functions.r")
```

Subsequently, we use the function `simcountdata()` to generate an example dataset with a sample size of N=2000. In this example, we have two disease modifying therapies (DMT1 and DMT0) and the outcome is the number of post-treatment multiple sclerosis relapses during follow-up.

```
# Randomization seed
base.seed <- 999

set.seed(base.seed)
df.ori <- simcountdata(n = 2000,
                       seed = 63,
                       beta = c(log(0.4), log(0.5), log(1), log(1.1), log(1.2)),
                       beta.x = c(-1.54, -0.01, 0.06, 0.25, 0.5, 0.13, 0.0000003)
)$data
```

The dataset looks as follows:

```
head(df.ori)
```

```
  trt ageatindex_centered female prerelapse_num prevDMTefficacy premedicalcost
1   0                   2      0              2    Low efficacy        4606.04
2   1                  10      1              1    Low efficacy       17065.19
3   1                  12      1              2            None        6308.39
4   1                 -12      0              0    Low efficacy       16633.97
5   1                  13      1              0    Low efficacy         642.96
6   1                  14      1              0    Low efficacy        2989.89
  numSymptoms postrelapse_num finalpostdayscount     group     score Iscore
1           0               1                305 Simulated 0.7129792      1
2           1               0                367 Simulated 0.7404238      2
3           0               0                325 Simulated 0.7564233      3
4           0               0                321 Simulated 0.7215764      1
5           0               0                 24 Simulated 0.7457823      2
6           0               0                 59 Simulated 0.7441632      2
```

Below is a summary table of the baseline characteristics by treatment group.

We now define key constants for the case study.

```r
# Baseline characteristics
covars <- c("age.z", "female", "prevtrtB", "prevtrtC", "prevnumsymp1",
            "prevnumsymp2p", "previous_cost.z", "previous_number_relapses")

# Precision medicine methods to be used
pm.methods <- c("all1", "all0", "poisson", "dWOLS", "listDTR2",
                "contrastReg")

# Precision medicine method labels
method.vec <- c("All 0", "All 1", "Poisson", "dWOLS",
                "Contrast\n Regression", "List DTR\n (2 branches)")

# Number of folds in each CV iteration
n.fold <- 5

# Number of CV iterations
n.cv <- 10

# Sample size of the large independent test set to get true value
big.n <- 100000

# Define formula for the CATE model
cate.formula <- as.formula(paste0("y ~", paste0(covars, collapse = "+"),
```

Table 9.1: Baseline characteristics of the case study data

	0	1	Overall
	(N=506)	(N=1494)	(N=2000)
Age (years)			
Mean (SD)	45.2 (9.82)	45.8 (9.73)	45.7 (9.75)
Median [Min, Max]	46.0 [20.0, 64.0]	46.0 [19.0, 64.0]	46.0 [19.0, 64.0]
Gender			
female	375 (74.1%)	1123 (75.2%)	1498 (74.9%)
male	131 (25.9%)	371 (24.8%)	502 (25.1%)
Previous number of relapses			
0	319 (63.0%)	973 (65.1%)	1292 (64.6%)
1	150 (29.6%)	427 (28.6%)	577 (28.9%)
2	31 (6.1%)	76 (5.1%)	107 (5.4%)
3	5 (1.0%)	17 (1.1%)	22 (1.1%)
4	1 (0.2%)	1 (0.1%)	2 (0.1%)
Efficacy of previous disease modifying therapy			
Low efficacy	216 (42.7%)	609 (40.8%)	825 (41.3%)
Medium and high efficacy	53 (10.5%)	179 (12.0%)	232 (11.6%)
None	237 (46.8%)	706 (47.3%)	943 (47.2%)
Previous medical cost (\$)			
Mean (SD)	13700 (20400)	14400 (24500)	14300 (23600)
Median [Min, Max]	7320 [343, 264000]	7560 [110, 556000]	7470 [110, 556000]
Previous number of symptoms			
0	348 (68.8%)	995 (66.6%)	1343 (67.2%)
1	119 (23.5%)	388 (26.0%)	507 (25.4%)
>=2	39 (7.7%)	111 (7.4%)	150 (7.5%)

```
                                    "+ offset(log(years))"))

# Define formula for the propensity score model
ps.formula <- trt ~ age.z + prevtrtB + prevtrtC

# Color
myblue <- rgb(37, 15, 186, maxColorValue = 255)
mygreen <- rgb(109, 173, 70, maxColorValue = 255)
mygrey <- rgb(124, 135, 142, maxColorValue = 255)
```

The data need to be preprocessed to be more analyzable. We recategorized treatment, previous treatment, and number of symptoms; scaled medical cost and age; and standardized the data.

```
df <- df.ori %>%
  rename(previous_treatment = prevDMTefficacy,
         age = ageatindex_centered,
         y = postrelapse_num,
         previous_number_relapses = prerelapse_num,
         previous_number_symptoms = numSymptoms,
         previous_cost = premedicalcost) %>%
  mutate(previous_treatment = factor(previous_treatment,
                                     levels = c("None", "Low efficacy", "Medium and high e
                                     labels = c("drugA", "drugB", "drugC")),
         previous_number_symptoms = factor(previous_number_symptoms,
                                           levels = c("0", "1", ">=2"),
                                           labels = c("0", "1", ">=2")),
         trt = factor(trt, levels = c(0, 1), labels = c("drug0", "drug1")),
         previous_cost.z = scale(log(previous_cost), scale = TRUE), # log-transformed due
         age.z = age + 48,
         age.z = scale(age.z, scale = TRUE),
         years = finalpostdayscount / 365.25,
         mlogarr0001 = -log(y / years + 0.001),
         drug1 = as.numeric(trt == "drug1"),
         prevtrtB = as.numeric(previous_treatment == "drugB"),
         prevtrtC = as.numeric(previous_treatment == "drugC"),
         prevnumsymp1 = as.numeric(previous_number_symptoms == "1"),
         prevnumsymp2p = as.numeric(previous_number_symptoms == ">=2")) %>%
  dplyr::select(age.z, female, contains("prevtrt"), previous_cost.z, contains("prevnumsymp
                previous_number_relapses, trt, drug1, y, mlogarr0001, years, Iscore)

# Standardize data
```

```r
df.s <- df
df.s[, setdiff(covars, c("age.z", "previous_cost.z"))] <- df[, setdiff(covars, c("age.z",
```

9.1 Estmition of individualized treatment rules

The following code provides details of how to implement the precision medicine methods in the example data. Please feel free to jump to the next section if you want to focus on the results. The model results are available online for you to load and save time.

We used the function `listdtr()` in the `listdtr` package to estimate ITRs based on the listDTR method. We used the function `catefit()` in the `PrecMed` package to estimate ITRs based on the Poisson and contrast regression method. These were the methods used in Section 3 where we talked about directly visualizing the ITR before bringing in the outcomes.

```r
library(listdtr)

# Estimated ITR based on the listDTR method with 2 branches
modlist2 <- listdtr(y = df$mlogarr, # larger is more favorable
                    a = df$drug1,
                    x = df[, c("age.z", "female", "prevtrtB", "prevtrtC", "previous_cost.z"
                               "prevnumsymp1", "prevnumsymp2p", "previous_number_relapses")
                    stage.x = rep(1, 8), maxlen = 2L) # somewhat slow

# Estimated ITR based on the listDTR method with 3 branches
modlist3 <- listdtr(y = df$mlogarr,
                     a = df$drug1,
                     x = df[, c("age.z", "female", "prevtrtB", "prevtrtC", "previous_cost.z
                                "prevnumsymp1", "prevnumsymp2p", "previous_number_relapses"
                     stage.x = rep(1, 8), maxlen = 3L) # somewhat slow

# Estimated CATE score based on the Poisson and contrast regression
modpm <- catefit(response = "count",
            cate.model = cate.formula,
            ps.model = ps.formula,
            data = df,
            higher.y = FALSE,
            score.method = c("poisson", "contrastReg"),
            initial.predictor.method = "poisson",
            seed = 999)
```

```
# Estimated CATE score based on the Poisson and contrast regression
# (based on the scaled data so the coefficients are easier to compare)
modpm.s <- catefit(response = "count",
                   cate.model = cate.formula,
                   ps.model = ps.formula,
                   data = df.s,
                   higher.y = FALSE,
                   score.method = c("poisson", "contrastReg"),
                   initial.predictor.method = "poisson",
                   seed = 999)
```

For results in Sections 4 and 5, we applied cross validation to mitigate over-fitting. For this chapter, we created our own customized function `cvvalue()` to estimate the ITR and calculate the estimated value function via cross validation for all methods, including the fixed method. The results were all saved under the prefix `cvmod`. The `PrecMed` package has a built-in cross validation procedure for CATE estimation so we used the function `catefit()`.

```
# Run cross validation for each method (used for Sections 4 & 5)

## Estimated CATE scores based on the Poisson and contrast regression with cross-validatio
modcv <- catecv(response = "count",
                cate.model = cate.formula,
                ps.model = ps.formula,
                data = df,
                higher.y = FALSE,
                score.method = c("poisson", "contrastReg"),
                initial.predictor.method = "poisson",
                cv.n = n.cv,
                plot.gbmperf = FALSE,
                seed = 999) # somewhat slow

## Estimated value function for each method
cvmodall0 <- cvvalue(data = df, xvar = covars,
                     method = "all0", n.fold = n.fold, n.cv = n.cv,
                     seed = base.seed)

cvmodall1 <- cvvalue(data = df, xvar = covars,
                     method = "all1", n.fold = n.fold, n.cv = n.cv,
                     seed = base.seed)

cvmoddwols <- cvvalue(data = df, xvar = covars,
                      method = "dWOLS", n.fold = n.fold, n.cv = n.cv,
```

```
                      seed = base.seed)

cvmodpois <- cvvalue(data = df, xvar = covars,
                     method = "poisson", n.fold = n.fold, n.cv = n.cv,
                     seed = base.seed)

cvmodlist2 <- cvvalue(data = df, xvar = covars,
                      method = "listDTR2", n.fold = n.fold, n.cv = n.cv,
                      seed = base.seed) # very slow

cvmodcontrastreg <- cvvalue(data = df, xvar = covars,
                            method = "contrastReg", n.fold = n.fold,
                            n.cv = n.cv,
                            seed = base.seed) # very slow
```

As a next step, we need to combine all estimated ITRs and value functions:

```
# Combine CV results
# Read in each CV result in a loop
vhats.dhat <- dhats <- NULL
mod_names <- c("cvmodall1", "cvmodall0", "cvmoddwols", "cvmodpois", "cvmodcontrastreg", "c
for (mod in mod_names){
  thismod <- get(mod)
  for (name in names(thismod)) {
    # Get estimated values, vhat.dhat
    vhats.dhat <- rbind(vhats.dhat,
                        thismod[[name]] %>%
                          map_df(~bind_rows(names(.x) %>% str_detect("vhat.dhat") %>% keep
                          mutate(method = mod, cv.i = name))
    # Get estimated rule from CV test fold, dhat
    dhats  <- rbind(dhats,
                    thismod[[name]] %>%
                      map_df(~bind_rows(names(.x) %>% str_detect("^dhat$") %>% keep(.x, .)
                      mutate(method = mod, cv.i = name))

  }
}

# One time run to get true optimal and worst value
# Simulated data only
trueV <- getTrueOptimalValue(n = big.n, seed = base.seed)
```

```r
trueWorstV <- getTrueWorstValue(n = big.n, seed = base.seed)

# Preprocess
vhats.dhat %<>%
  mutate(V = U/W,
         VR = (U/W - trueWorstV) / (trueV - trueWorstV)) %>%
  group_by(method) %>%
  summarize(n.batches = n(),
            n.nonnaU = sum(!is.na(U)),
            n.nonnaW = sum(!is.na(W)),
            meanV = mean(V, na.rm = T),
            sdV = sd(V, na.rm = T),
            meanVR = mean(VR, na.rm = T),
            sdVR = sd(VR, na.rm = T),
            .groups = "keep") %>%
  ungroup %>%
  arrange(desc(meanV)) %>%
  mutate(method = case_when(
    method == "cvmodcontrastreg" ~ "Contrast\n Regression",
    method == "cvmodall0" ~ "All 0",
    method == "cvmodall1" ~ "All 1",
    method == "cvmodlist2" ~ "List DTR\n (2 branches)",
    method == "cvmoddwols" ~ "dWOLS",
    method == "cvmodpois" ~ "Poisson"),
    method = factor(method,
                    levels = method.vec,
                    labels = method.vec)
  )

dhats %<>%
  mutate(method = case_when(
    method == "cvmodcontrastreg" ~ "Contrast\n Regression",
    method == "cvmodall0" ~ "All 0",
    method == "cvmodall1" ~ "All 1",
    method == "cvmodlist2" ~ "List DTR\n (2 branches)",
    method == "cvmoddwols" ~ "dWOLS",
    method == "cvmodpois" ~ "Poisson"),
    method = factor(method,
                    levels = method.vec,
                    labels = method.vec)
  )
```

9.2 Visualization of individualized treatment rules

9.2.1 Direct visualization

9.2.1.1 listDTR

If the PM method already has built-in visualization (especially for tree-based methods), we can visualize the ITR directly. For example, we can simply use the function `plot()` to visualize the estimated ITR with the listDTR method.

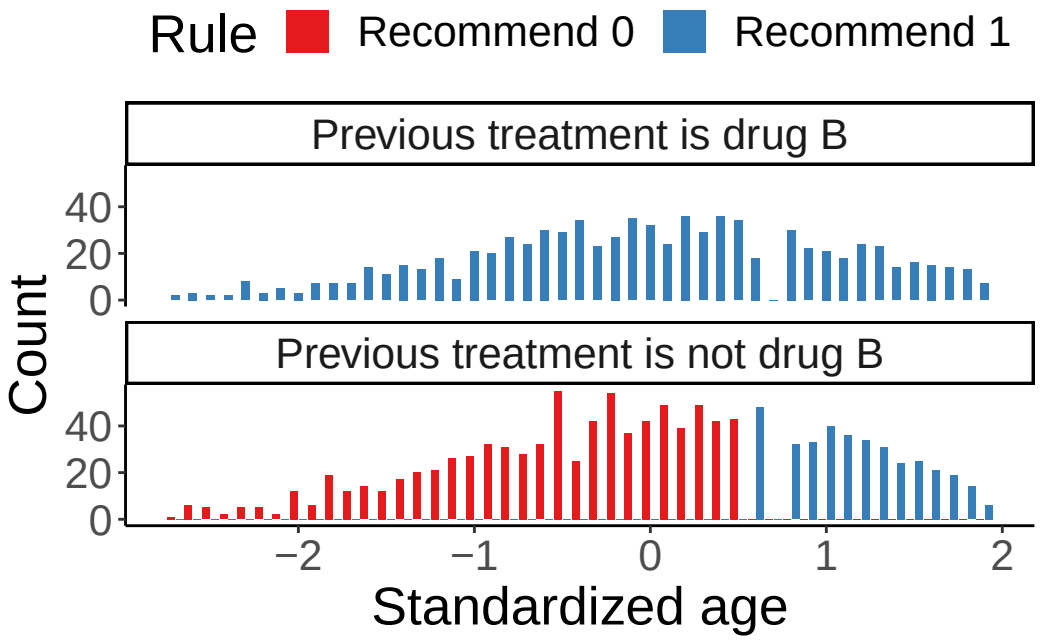
```
#modlist3 %>% plot()
```

We can also create our own visualization like Figure 1A in the chapter.

```
df.list3 <- df %>%
  mutate(d.list = ifelse(age.z > 0.599 | prevtrtB > 0.5, "Recommend 1", "Recommend 0"), #
         Rule = factor(as.character(d.list), levels = c("Recommend 0", "Recommend 1")),
         prevtrtB = ifelse(prevtrtB == 1, "Previous treatment is drug B", "Previous treatm
  )

## Figure 1A
df.list3 %>%
  ggplot(aes(x = age.z, fill = Rule))+
  geom_histogram(position = position_dodge2(preserve = 'single'), binwidth = 0.1)+
  facet_wrap(~ prevtrtB, nrow = 2) +
  scale_fill_brewer(palette = "Set1") +
  labs(x = "Standardized age", y = "Count") +
  theme_classic() +
  theme(legend.position = 'top', text = element_text(size = 20))
```

Observed treatment	listDTR ITR	ARR	n	prop%
drug0	Recommend 0	0.32	197	10
drug0	Recommend 1	0.31	309	15
drug1	Recommend 0	0.39	615	31
drug1	Recommend 1	0.16	879	44



The subgroup-level annualized relapse rate (ARR) can be calculated based on the listDTR ITR:

```
df.list3 %>%
  group_by(trt, d.list) %>%
  summarise(ARR = round(sum(y) / sum(years), 2),
            n = n(),
            `prop%` = round(n / nrow(df), 2)*100, .groups = "drop") %>%
  rename("listDTR ITR" = d.list,
         "Observed treatment" = trt) %>%
  kable() %>%
  kable_styling(full_width = F)
```

Patients who received drug 0 and were recommended drug 0 by listDTR had a similar ARR on average than those who received drug 0 but were recommended drug 1 (0.32 vs 0.31). Patients who received drug 1 and were recommended drug 1 by listDTR had a much lower ARR on average than those who received drug 1 but were recommended drug 0 (0.16 vs 0.39).

9.2.1.2 Score-based method

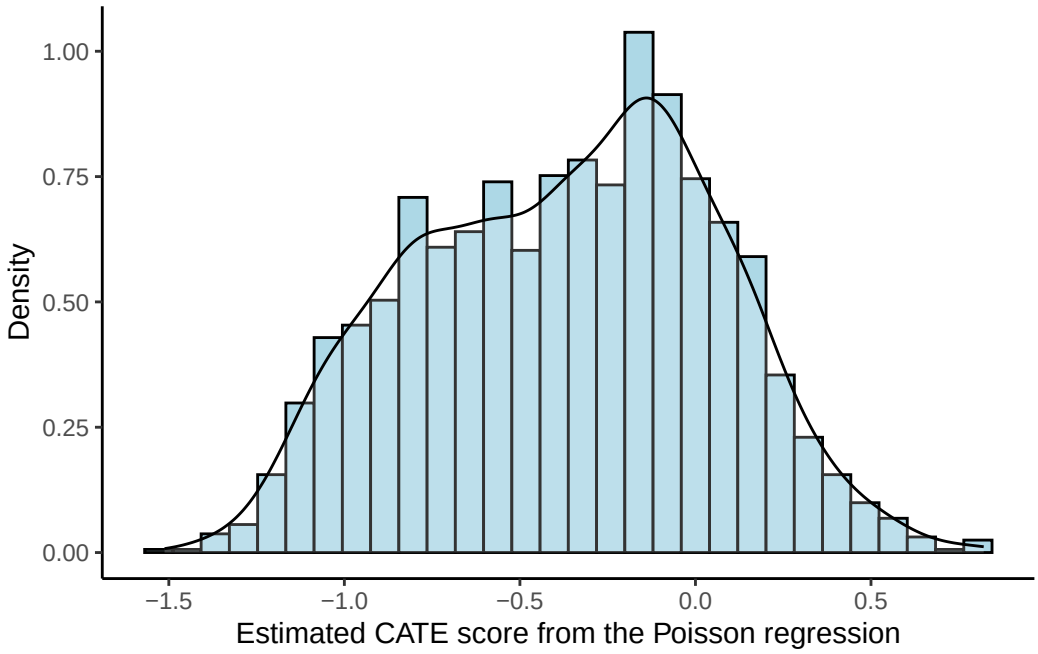
Although some PM methods do not have built-in visualization or not as "white-box" as some more interpretable methods, there still might be ways to visualize the ITR. For example, score-based methods (such as Poisson and contrast regression) produce an estimate of the CATE score for each patient, and a classification tree can be fitted on these scores and visualized. Below is a histogram-density plot of the CATE scores estimated from the Poisson regression and the fitted classification tree using the estimated CATE scores. We pruned the tree so it only had three nodes for simplicity. The `rpart.plot` package has a built-in visualization function of the `rpart` model, `rpart.plot()`, which is how Figure 1B in the chapter was generated.

```
df["score.poisson"] <- modpm$score.poisson

ggplot(df, aes(x = score.poisson)) +
  geom_histogram(aes(y = ..density..), colour = "black", fill = "lightblue") +
  geom_density(alpha = .2, fill = "white") +
  labs(x = "Estimated CATE score from the Poisson regression", y = "Density") +
  theme_classic()
```

```
Warning: The dot-dot notation (`..density..`) was deprecated in ggplot2 3.4.0.
i Please use `after_stat(density)` instead.
```

```
`stat_bin()` using `bins = 30`. Pick better value with `binwidth`.
```

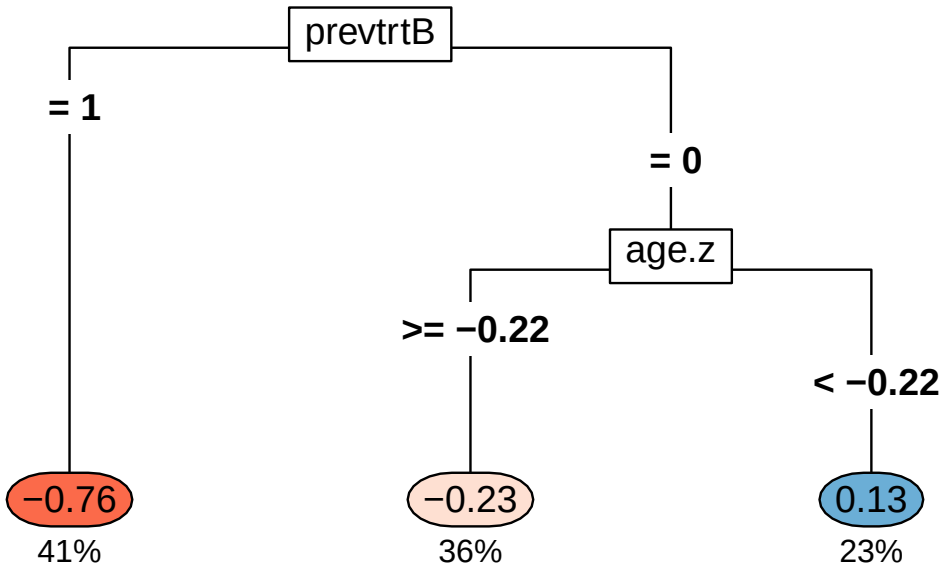


```
modtree <- rpart(as.formula(paste0("score.poisson ~", paste0(covars, collapse = "+"))),
                 method = "anova", data = df, control = rpart.control(minsplit = 100, cp =

modtree.pr <- prune(modtree, cp = 0.09) # I ended up choosing a higher cp value to have on

# print(rpart.rules(modtree.pr, cover = TRUE))

## Figure 1B
rpart.plot(modtree.pr, box.palette = "RdBu", type = 5, under = TRUE, tweak = 1.2, compress
```



The CATE scores are now simplified as a tree classifier. Previous treatment of drug B and age seemed to be important in determining the CATE score values, which also showed up in the estimated from the listDTR method. Patients with previous treatment of drug B had the lowest CATE score on average (-0.76) and took up 41% of the samples (dark orange). Patients whose previous treatment was not drug B and age was >= -0.22 standard deviation of the mean also had a negative CATE score on average (-0.23) and took up 36% of the samples (light orange), but not as low as the dark orange group. Negative CATE scores mean that the number of relapses was expected to be lower for those recommended drug 1 than those recommended drug 0, so drug 1 was favored for them. For the blue group, the average CATE score was 0.13, taking up 23% of the samples, and they were expected to benefit from drug 0 based on the Poisson CATE scores.

9.2.2 ITR accuracy

The accuracy of ITR is the proportion of patients whose estimated ITR is the same as the true optimal ITR. The estimated ITRs have been obtained from the PM methods but we need to calculate the true optimal ITR. This is only possible for simulated data where the decision boundary is known. Based on the data generating mechanism in `simcountdata()`, `Iscore` is a score generated from a linear combination of baseline covariates where lower scores represented that drug 1 was better and higher scores represented that drug 0 was better. We then classified patients in 5 equal-size subgroups based on the `Iscore`, where groups 1 and 2 have drug 1 as their true optimal ITR and groups 3 and 4 have drug 0 as their true optimal ITR. Group 3 is considered the neutral group, where patients are indifferent to either drug so we assign the true optimal ITR to be their observed treatment. Thus, we identify the true optimal ITR for every patient based on this subgrouping, which was derived from their true

score `Iscore`. Since we used cross validation in estimating the ITR, we need to apply the exact same cross validation to the true optimal ITR. This is achieved by specifying the same randomization seed in the cross validation loop (see `seed`).

```
## Create new columns
dhats$d <- rep(NA, nrow(dhats)) # true d

# Identify the true optimal treatment
# See simcountdata() in the function script to learn more about Iscore
sim <- df %>%
  mutate(trueT = ifelse(as.numeric(Iscore) < 3, 1, 0),
         trueT = ifelse(Iscore == 3, drug1, trueT)) # neutral group

# Format data
input <- data.frame(y = sim$y, trt = sim$drug1, time = log(sim$years), sim[covars])

# Cross validation loop
for(i in unique(dhats$cv.i)) {
  seed <- base.seed*100 + as.numeric(str_extract(i, "[0-9]+"))
  set.seed(seed)

  # Create CV folds
  folds <- createFolds(input$trt, k = n.fold, list = TRUE) # Stratified CV, follow the sam

  for (fold.i in 1:n.fold){
    testdata <- sim[folds[[fold.i]],]
    # number of methods which succeeded for the given fold/batch. The "is.na(dhat) == FALS
    nr <- nrow(dhats %>% filter(fold == paste0("fold", fold.i), cv.i == i, is.na(dhat) ==
    dhats$d[which(dhats$fold == paste0("fold", fold.i) & dhats$cv.i == i & is.na(dhats$dha
    stopifnot(nr %% nrow(testdata) == 0)
  }
} # end of all cv iterations
```

Once we identified the true optimal ITR (d^{opt}), we can calculate the accuracy in each validation fold for each PM method ($\hat{d}_{pm}$). Mathematically, accuracy can be expressed as

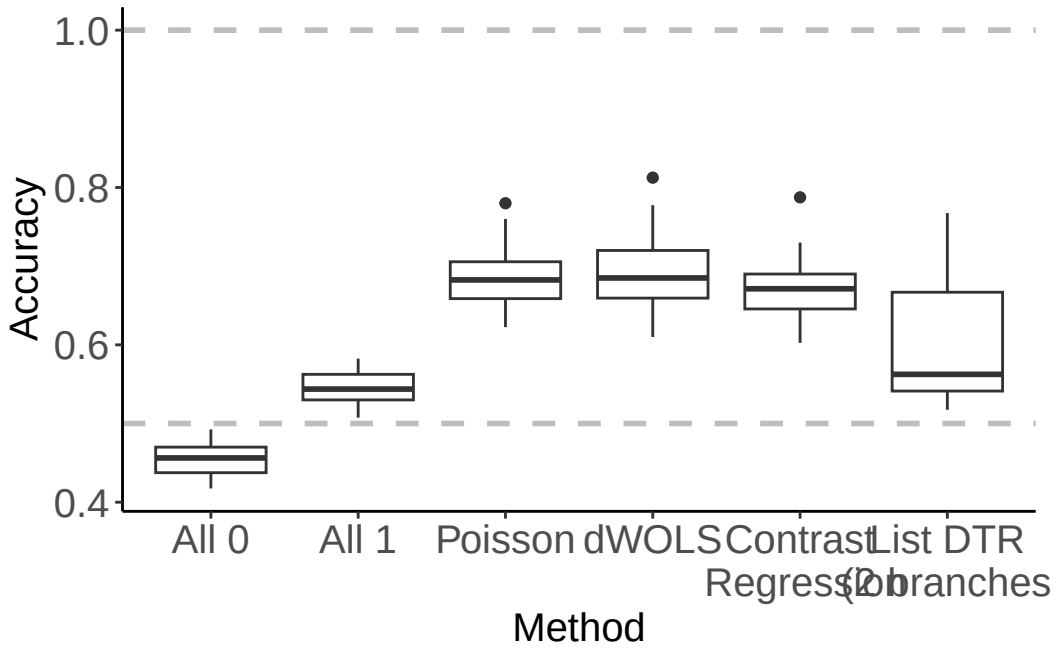
$$Accuracy_{pm}(x^{val}) = \frac{1}{n^{val}} \sum_{i=1}^{n^{val}} I(\hat{d}_{pm}(x_i^{val}) == d^{opt}(x_i^{val})),$$

where n^{val} is the sample size in the validation fold, x_i^{val} is the baseline characteristics of the ith patient in the validation fold, and pm stands for one PM method.

Below is how Figure 2 in the chapter was generated. It summarized the accuracy across all validation folds as a box plot so we can also learn the variability of accuracy across folds.

```r
##### Accuracy #####
## Calculate % accuracy for each iteration & summary statistics
dhats.accuracy <- dhats %>%
  group_by(method, cv.i, fold) %>%
  summarise(accuracy = sum(dhat == d)/n(), .groups = "drop") %>%
  ungroup

## Make the accuracy plot, Figure 2
dhats.accuracy %>%
  ggplot(aes(x = method, y = accuracy)) +
  geom_boxplot() +
  geom_hline(yintercept = 1, linetype = 2, linewidth = 1, color = "gray") +
  geom_hline(yintercept = 0.5, linetype = 2, linewidth = 1, color = "gray") +
  theme_classic() +
  labs(x = "Method", y = "Accuracy") +
  theme(axis.text = element_text(size = 15),
        axis.title.y = element_text(size = 15),
        axis.title.x = element_text(size = 15),
        axis.text.x = element_text(angle = 0, size = 15),
        strip.text.x = element_text(size = 15))
```



9.2.3 ITR agreement

When we do not know the true data generating mechanism, e.g., real-world data, we cannot compare the estimated ITR with the true optimal ITR. However, we can compare the estimated ITR with another estimated ITR, and this is called agreement. Agreement is the proportion of patients whose estimated ITR of a method is the same as the estimated ITR of another method. Thus, agreement is between two methods. Mathematically,

$$Agreement_{1,2}(x^{val}) = \frac{1}{n^{val}} \sum_{i=1}^{n^{val}} I(\hat{d}_1(x^{val}) == \hat{d}_2(x^{val})),$$

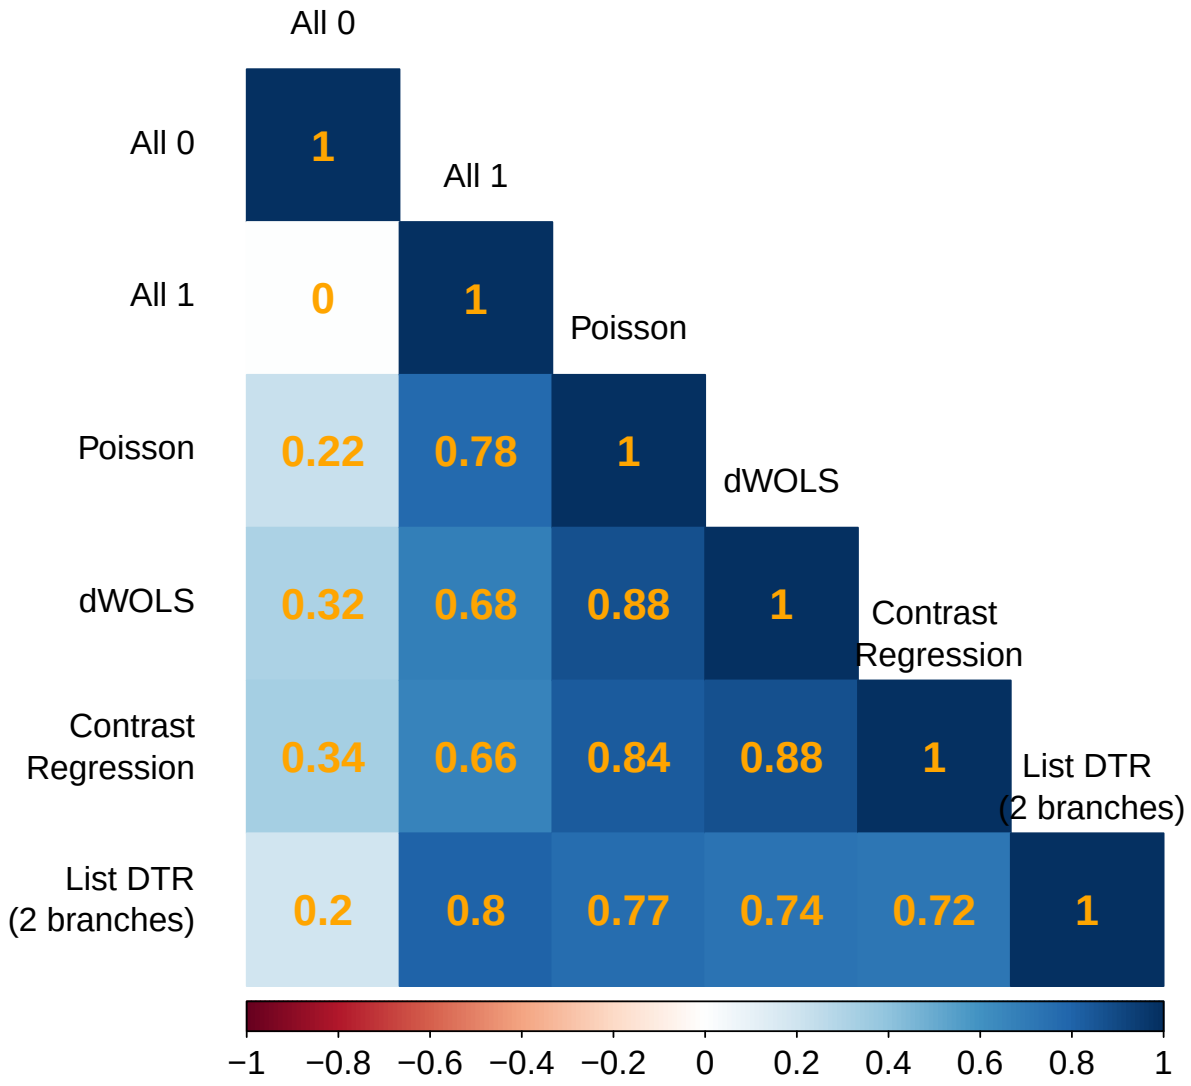
where n^{val} is the sample size in the validation fold, x_i^{val} is the baseline characteristics of the ith patient in the validation fold, and $1, 2$ stands for method 1 and method 2.

```
##### Agreement #####
dhats.concat <- dhats %>%
  arrange(cv.i, fold, method) %>%
  mutate(iteration.fold = (as.numeric(str_extract(cv.i, "[0-9]+")) - 1) * 10 + as.numeric(
  dplyr::select(method, iteration.fold, dhat) %>%
  group_by(method, iteration.fold) %>%
  mutate(i = 1:n()) %>%
  ungroup

m <- length(method.vec)
dhats.agreement <- matrix(nrow = m, ncol = m)
colnames(dhats.agreement) <- method.vec
rownames(dhats.agreement) <- method.vec

for(k in seq_len(m)){
  for(j in seq(k, m)){
    data.k <- dhats.concat %>% filter(method == method.vec[k])
    data.j <- dhats.concat %>% filter(method == method.vec[j])
    data.jk <- data.k %>% full_join(data.j, by = c("iteration.fold", "i"))
    dhats.agreement[k, j] <- dhats.agreement[j, k] <- sum(data.jk$dhat.x == data.jk$dhat.y
  }
}

# Make the agreement plot, Figure 3
corrplot(dhats.agreement, method = "color",  type = "lower",
         addCoef.col = "orange", number.cex = 1.5,
         tl.cex = 1.2, cl.cex = 1.2, tl.col = "black", tl.srt = 0, tl.offset = 1.5)
```



We used the `corrplot` package to generate Figure 3 in the chapter but agreement can be visualized in other creative ways that you prefer.

9.3 Section 4. Patient well-being

Patient well-being is evaluated via the value function, which is defined as the expected outcome had they followed the specified ITR. Like a fortune teller's crystal ball, this metric tells us how well the patients would do on average under each ITR. We can then compare across different ITRs and identify an optimal ITR. Cross validation is necessary here to mitigate over-fitting, and we visualized the value function results as error bar plots. The mean and

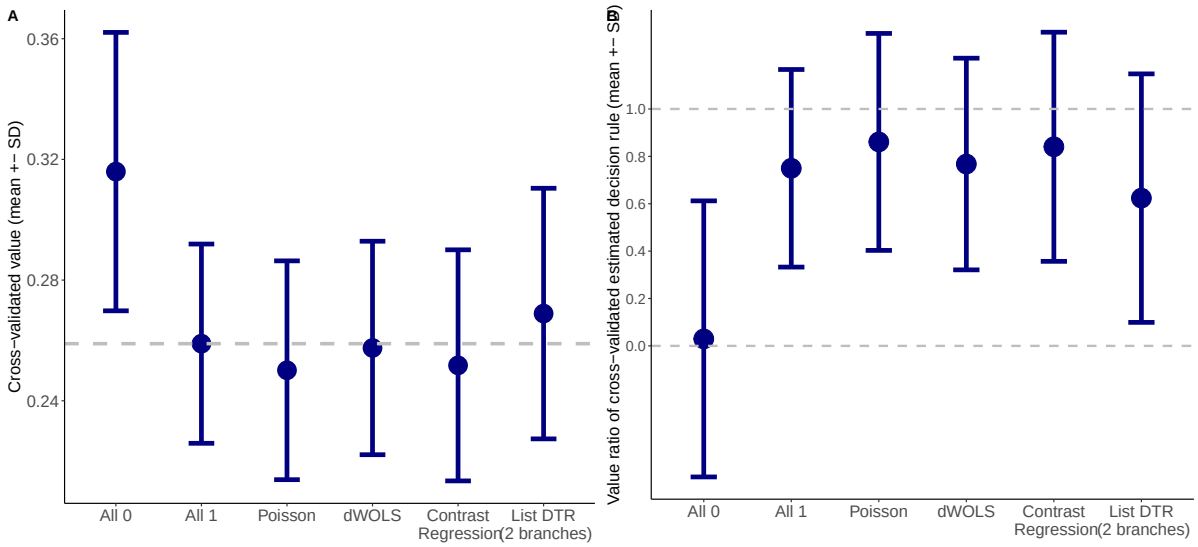
standard deviation of the value functions have been preprocessed previously. We use `ggplot()` to generate the error bar plots. Figure 4A is the original value function estimates, and Figure 4B is the standardized value ratio estimates, which convert value functions to a ratio where 1 is always more desirable.

```
##### Errorbar plot #####
# Figure 4A
p4a <- vhats.dhat %>%
  ggplot(aes(x = method, y = meanV)) +
  geom_point(size = 8, shape = 16, color = "navy") +
  geom_errorbar(aes(ymin = meanV - sdV, ymax = meanV + sdV), width = 0.3, size = 2, positi
  theme_classic() + xlab("") + ylab("Cross-validated value (mean +- SD)") +
  theme(axis.text = element_text(size = 15), axis.title.y = element_text(size = 15)) +
  geom_hline(yintercept = vhats.dhat$meanV[which(vhats.dhat$method == "All 1")], linetype
```

```
Warning: Using `size` aesthetic for lines was deprecated in ggplot2 3.4.0.
i Please use `linewidth` instead.
```

```
##### Value ratio #####
# Figure 4B
p4b <- vhats.dhat %>%
  dplyr::select(method, contains("VR"), n.nonnaU) %>%
  ggplot(aes(x = method, y = meanVR)) +
  geom_point(size = 8, color = "navy") +
  geom_errorbar(aes(ymin = meanVR - sdVR, ymax = meanVR + sdVR), width = 0.3, size = 2, po
  geom_hline(yintercept = 1, color = "gray", linetype = 2, size = 1) +
  geom_hline(yintercept = 0, color = "gray", linetype = 2, size = 1) +
  scale_y_continuous(breaks = seq(0, 1, length = 6)) +
  theme_classic() +
  labs(x = "", y = "Value ratio of cross-validated estimated decision rule (mean +- SD)")
  theme(axis.text = element_text(size = 13),
        axis.title.y = element_text(size = 15),
        axis.title.x = element_text(size = 15),
        axis.text.x = element_text(size = 15),
        strip.text.x = element_text(size = 12))

# Figure 4
ggarrange(p4a, p4b, ncol = 2, nrow = 1, labels = c("A", "B"))
```



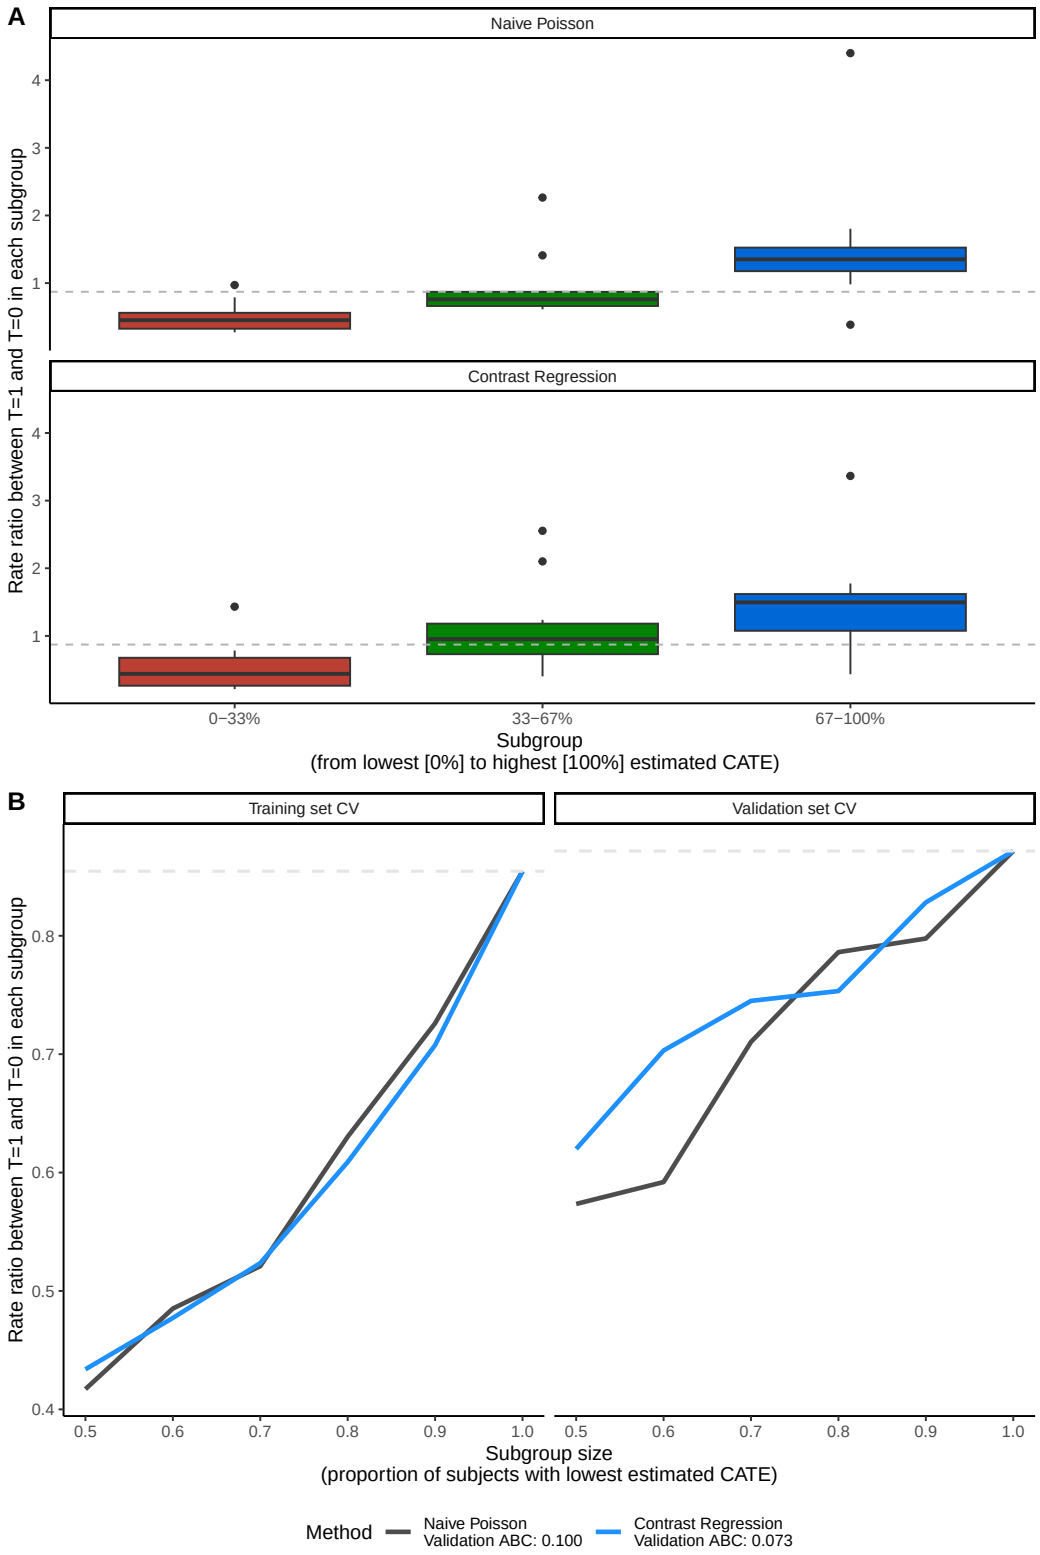
9.4 Section 5. Responder diagnostics

9.4.1 Validation

The package we used for the two score-based methods (Poisson and contrast regression), `PrecMed`, has built-in visualization tools to diagnose the results: validation box plots `boxplot()`, validation curves `plot()`, and area between curves (ABC) statistics `abc()`.

```
##### Validation of ITR scores #####
# Figure 5A
p5a <- boxplot(modcv, ylab = "Rate ratio between T=1 and T=0 in each subgroup")
# Figure 5B
p5b <- plot(modcv, ylab = "Rate ratio between T=1 and T=0 in each subgroup")

# Figure 5
ggarrange(p5a, p5b, ncol = 1, nrow = 2, labels = c("A", "B"))
```



A
Naive Poisson
Contrast Regression
Rate ratio between T=1 and T=0 in each subgroup
0−33%
33−67%
67−100%
Subgroup
(from lowest [0%] to highest [100%] estimated CATE)
B
Training set CV
Validation set CV
Rate ratio between T=1 and T=0 in each subgroup
Subgroup size
(proportion of subjects with lowest estimated CATE)
Method
Naive Poisson
Validation ABC: 0.100
Contrast Regression
Validation ABC: 0.073

The `PrecMed` package has more PM methods implemented other than Poisson and contrast regression that you can try, such as negative binomial and two regressions. See its documentation for more details.

9.4.2 Univariate comparision of patient characteristics

The 60/40 cutoff was used in the chapter to split patients into "high responders" and "standard responders". The function `CreateTableOne()` in the `tableone` package was used to generate a table comparing side-by-side the baseline characteristics between the two responder groups.

```
##### Side-by-side baseline characteristic comparison between responder subgroups #####
cutoff <- quantile(modpm$score.poisson, 0.6) # 60/40 high vs standard responder split
df["responder to T=1"] <- ifelse(modpm$score.poisson < cutoff, "High", "Standard")
df["age.z"] <- as.numeric(df$age.z)
df["previous_cost.z"] <- as.numeric(df$previous_cost.z)

labs <- list("age.z" = "Standardized baseline age", "female" = "Female",
             "prevtrtB" = "Previous treatment drug B", "prevtrtC" = "Previous treatment dr
             "prevnumsymp1" = "Previous number of symptoms == 1",
             "prevnumsymp2p" = "Previuos number of symptoms >= 2",
             "previous_cost.z" = "Standardized previous medical cost\n(excluding medicatio
             "previos_number_relapses" = "Previous number of relapses")

tab <- CreateTableOne(vars = covars, strata = "responder to T=1", data = df, test = F) %>%
```

```
                                  Stratified by responder to T=1
                                   High          Standard      SMD
n                                    1200            800
age.z (mean (SD))                    0.29 (0.94) -0.44 (0.92)  0.789
female (mean (SD))                   0.69 (0.46)  0.84 (0.36)  0.384
prevtrtB (mean (SD))                 0.67 (0.47)  0.02 (0.15)  1.867
prevtrtC (mean (SD))                 0.02 (0.13)  0.26 (0.44)  0.750
prevnumsymp1 (mean (SD))             0.33 (0.47)  0.15 (0.35)  0.431
prevnumsymp2p (mean (SD))            0.05 (0.22)  0.11 (0.31)  0.208
previous_cost.z (mean (SD))         -0.08 (1.00)  0.12 (0.99)  0.203
previous_number_relapses (mean (SD)) 0.41 (0.64)  0.47 (0.68)  0.104
```

We can directly present the table or visualize the comparison with errorbar plots, which is what the chapter presented (Figure 6A). Here we show both. Tables are helpful if specific numbers are important but readers would have to perform mental comparison to understand

which value is higher, whereas plots are helpful if you want people to quickly identify the larger differences and not focus on the specific values of certain results.

```
smd <- as_tibble(tab, rownames = "var") %>%
  rowwise() %>%
  mutate(variable = as.factor(str_extract(var, ".*(?= \\(mean \\(SD\\)\\))"))) %>%
  filter(!is.na(variable)) %>%
  arrange(desc(SMD)) %>%
  mutate(smd = paste0("SMD =", SMD),
         variable = labs[[variable]]) %>%
  dplyr::select(variable, smd) %>%
  mutate(ID = 1)

levels <- unique(smd$variable)

p6a <- df %>%
  mutate(ID = 1:n()) %>%
  dplyr::select(all_of(covars), ID, contains("responder")) %>%
  melt(id = c("ID", "responder to T=1")) %>%
  rowwise() %>%
  mutate(variable = labs[[variable]]) %>%
  left_join(smd, by = c("variable", "ID")) %>%
  mutate(variable2 = factor(variable, levels = levels)) %>%
  ggplot(aes(x = reorder(variable2, desc(variable2)), color = `responder to T=1`, y = valu
  stat_summary(fun = mean, geom = "point", size = 4, position = position_dodge(width = 0.5
  stat_summary(fun.data = mean_sdl, geom = "errorbar", position = position_dodge(width = 0

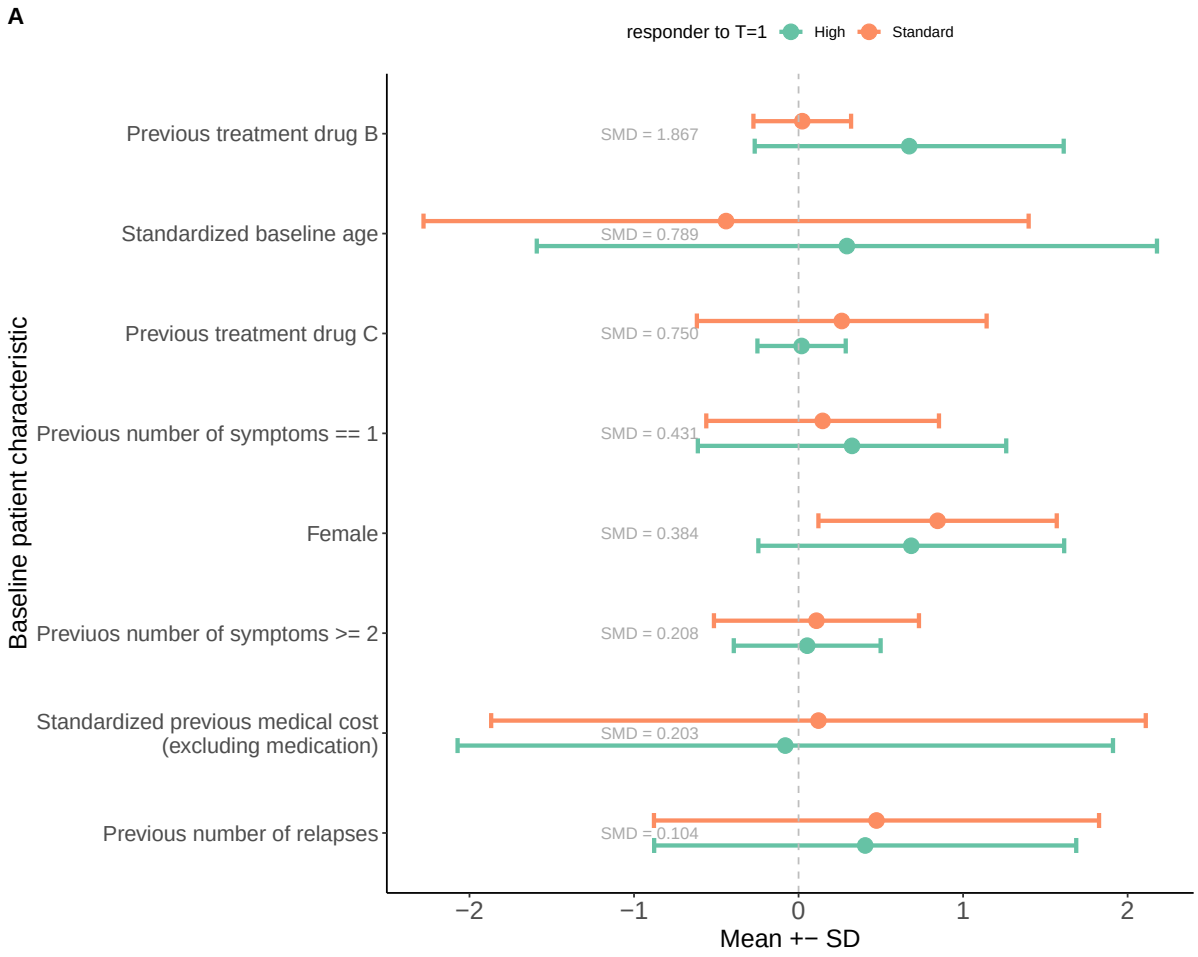
  theme_classic() +
  theme(legend.position = "top",
        axis.text = element_text(size = 13),
        axis.title.y = element_text(size = 15),
        axis.title.x = element_text(size = 15),
        axis.text.x = element_text(size = 15),
        strip.text.x = element_text(size = 12))

# Figure 6A
```

```
ggarrange(p6a, nrow = 1, labels = c("A"))
```



We can also show the density of ITR scores obtained from the score-based methods. The results can be found in `modpm` and we used histogram to visualize (Figure 6B).

```
##### Density of ITR score #####
dataplot <- data.frame(score = factor(rep(c("Naive Poisson", "Contrast Regression"),
                                          each = length(modpm$score.poisson))),
                       value = c(modpm$score.poisson, modpm$score.contrastReg))

p6b <- dataplot %>%
  ggplot(aes(x = value, fill = score)) +
  geom_density(alpha = 0.5) +
```

```
  scale_fill_manual(values = c("dodgerblue", "gray30")) +
  geom_vline(xintercept = 0, color = "darkgray", linetype = "dashed", size = 1) +
  labs(x = "Estimated CATE score", y = "Density", fill = "Method") +
  theme_classic() +
  theme(legend.position = c(0.2, 0.8),
        axis.text = element_text(size = 13),
        axis.title.y = element_text(size = 15),
        axis.title.x = element_text(size = 15),
        axis.text.x = element_text(size = 15),
        strip.text.x = element_text(size = 12))
```

The ITR scores are essentially a linear combination of the baseline characteristics, thus it might be also of interest for one to know the corresponding coefficients (or weights) which shows how much each baseline variable contributed to the ITR score. To make it comparable across different scales of the baseline variables, we used the scaled data and the model result `modpm.s` was used to extract the coefficients and visualize as a bar plot. The coefficients can be presented in a table as well.

```
# Coefficients
coef <- modpm.s$coefficients

p6c <- coef %>%
  as_tibble(rownames = "varname") %>%
  melt(id.vars = "varname") %>%
  filter(variable == "poisson", varname != "(Intercept)") %>%
  mutate(absval = abs(value),
         sign = ifelse(value > 0, "+", "-")) %>%
  arrange(absval) %>%
  mutate(varname = factor(varname, levels = unique(varname))) %>%
  ggplot(aes(x = varname, y = absval, fill = sign)) +
  geom_bar(stat = "identity", width = 0.5) +
  scale_fill_brewer(palette = "Set1") +
  scale_x_discrete(labels = labs) +
  coord_flip() +
  labs(y = "Absolute value of the estimated coefficient of CATE scores\nbased on Poisson r
  theme_minimal() +
  theme(legend.position = c(0.8, 0.2),
        axis.text = element_text(size = 13),
        axis.title.y = element_text(size = 15),
        axis.title.x = element_text(size = 15),
        axis.text.x = element_text(size = 15),
```

```
        strip.text.x = element_text(size = 12))

# Figure 6B, 6C
ggarrange(p6b, p6c, nrow = 2, labels = c("B", "C"))
```
