1 Dealing with missing data

In this example, we consider the estimation of comparative treatment effects in the absence of treatment-effect heterogeneity.

1.0.1 Prepare R environment

```
library(mice)
library(dplyr)
library(ggmice)
library(MatchThem)
```

1.0.2 Generating an observational dataset

We can simulate an observational dataset of N = 3000 patients as follows:

```
data_noHTE <- generate_data(n = 3000, seed = 1234)
```

This dataset does not (yet) contain any missing values;

The simulated dataset contains two treatment groups with differences in baseline characteristics. For example, the figure below shows that we have baseline imbalance in age.

1.0.3 Generating missing values

Missing values can be generated using the function getmissdata(), which considers the following patterns of missingness for the previous number of relapses (prerelapse num):

- 1. MAR: missingness depends on age and sex
- 2. MART: missingness depends on age, sex and the treatment variable treatment
- 3. MARTY: missingness depends on age, sex, treatment and the outcome variable y
- 4. MNAR: missingness depends on age, sex and prerelapse_num

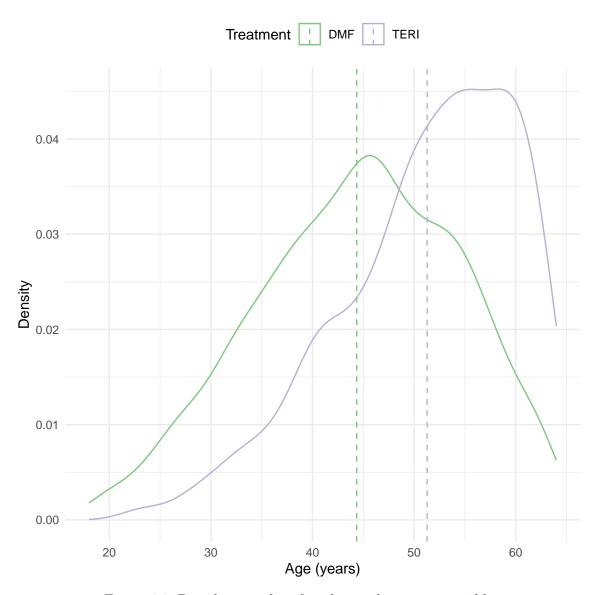

Figure 1.1: Distribution of confounders and outcome variable $\,$

```
mdata_noHTE <- getmissdata(data_noHTE, "MART")</pre>
```

After introducing missing values, we only have complete data for N=946 patients.

1.1 Analysis of incomplete data

1.1.1 Complete Case Analysis

Below, we describe how to estimate the ATE using propensity score matching.

```
impdata <- mdata_noHTE[complete.cases(mdata_noHTE), ]</pre>
  # Apply Matching
  mout <- matchit(DMF ~ age + female + prevDMTefficacy + premedicalcost + prerelapse_num,</pre>
                    data = impdata,
                    family = binomial,
                    method = "full",
                    caliper = 0.2,
                    estimand = "ATE",
                    replace = FALSE)
  mdata <- as.data.table(match.data(mout))</pre>
  match_mod <- glm("y ~ DMF + offset(log(years))",</pre>
                     family = poisson(link = "log"),
                     data = mdata,
                     weights = weights)
  # Estimate robust variance-covariance matrix
  tx_var <- vcovCL(match_mod, cluster = ~ subclass, sandwich = TRUE)</pre>
We can extract the treatment effect estimate as follows:
```

```
# Treatment effect estimate (log rate ratio)
coef(match_mod)["DMF"]
    DMF
```

-0.3524863

Table 1.1: Baseline characteristics of the incomplete dataset.

	DMF	TERI	Overall
	(N=2265)	(N=735)	(N=3000)
Age (years)			
Mean (SD)	44.4 (10.0)	51.3 (8.72)	46.2 (10.1)
Median [Min, Max]	45.0 [18.0, 64.0]	53.0 [23.0, 64.0]	47.0 [18.0, 64.0]
Missing	$248 \ (10.9\%)$	57 (7.8%)	$305\ (10.2\%)$
Female Sex			
Yes	$1740 \ (76.8\%)$	526 (71.6%)	2266~(75.5%)
No	525~(23.2%)	209 (28.4%)	$734\ (24.5\%)$
Efficacy of previous	\mathbf{DMT}		
None	740 (32.7%)	325 (44.2%)	1065 (35.5%)
Low	190 (8.4%)	59 (8.0%)	249 (8.3%)
Medium or High	830 (36.6%)	246 (33.5%)	1076 (35.9%)
Missing	$505\ (22.3\%)$	$105\ (14.3\%)$	$610\ (20.3\%)$
Prior medical costs			
Mean (SD)	9970 (10700)	25500 (35400)	13900 (21200)
Median [Min, Max]	6530 [164, 102000]	12500 [259, 337000]	7450 [164, 337000]
Missing	$257 \ (11.3\%)$	52 (7.1%)	$309\ (10.3\%)$
Number of prior sys	mptoms		
0	157 (6.9%)	58 (7.9%)	215 (7.2%)
1	1169 (51.6%)	411 (55.9%)	$1580 \ (52.7\%)$
>=2	435 (19.2%)	159 (21.6%)	594 (19.8%)
Missing	$504\ (22.3\%)$	$107 \ (14.6\%)$	$611\ (20.4\%)$
Number of prior rel	apses		
Mean (SD)	$0.453 \ (0.671)$	$0.408 \; (0.646)$	$0.436 \ (0.662)$
Median [Min, Max]	0 [0, 4.00]	0 [0, 3.00]	0 [0, 4.00]
Missing	1365~(60.3%)	$152\ (20.7\%)$	$1517 \ (50.6\%)$

```
# Standard error
sqrt(tx_var["DMF", "DMF"])
```

[1] 0.1498211

1.1.2 Multiple Imputation (within method)

In this approach, we will generate m=5 imputed datasets and perform matching within each imputed dataset. We first need to specify how the variables prevDMTefficacy, premedicalcost, numSymptoms, prerelapse_num and age will be imputed:

```
# We add a covariate for log(years)
impdata <- mdata_noHTE %>% mutate(logyears = log(years))
# Specify the conditional imputation models
form_y <- list(prevDMTefficacy ~ age + female + logyears + premedicalcost + numSymptoms +</pre>
                 treatment + prerelapse_num + y,
               premedicalcost ~ age + female + logyears + prevDMTefficacy + numSymptoms +
                 treatment + prerelapse_num + y,
               numSymptoms ~ age + female + premedicalcost + logyears + prevDMTefficacy +
                 prerelapse_num + treatment + y,
               prerelapse_num ~ age + female + premedicalcost + logyears + prevDMTefficacy
                 numSymptoms + treatment + y,
               age ~ prerelapse_num + female + premedicalcost + logyears + prevDMTefficacy
                 numSymptoms + treatment + y)
form_y <- name.formulas(form_y)</pre>
# Adopt predictive mean matching for imputing the incomplete variables
imp0 <- mice(impdata, form = form_y, maxit = 0)</pre>
method <- imp0$method
method["numSymptoms"] <- "pmm"</pre>
method["prevDMTefficacy"] <- "pmm"</pre>
# Generate 5 imputed datasets
imp <- mice(impdata, form = form_y, method = method, m = 5, maxit = 100)
```

We can now estimate the ATE using propensity score analysis in each of the imputed datasets. We here adopt full matching without replacement.

The results are then combined using Rubin's rules. We adopt robust standard errors to account for clustering of matched individuals.

We can extract the treatment effect estimate and corresponding standard error as follows:

```
# Treatment effect estimate (log rate ratio)
  (match_mod %>% filter(term == "DMF"))$estimate

[1] -0.1172783

# Standard error
  (match_mod %>% filter(term == "DMF"))$std.error

[1] 0.1895277
```

1.1.3 Multiple Imputation (across method)

```
family = binomial,
estimand = "ATE",
distance = "glm",
link = "logit",
replace = FALSE)
```

The results are then combined using Rubin's rules. We adopt robust standard errors to account for clustering of matched individuals.

We can extract the treatment effect estimate and corresponding standard error as follows:

```
# Treatment effect estimate (log rate ratio)
  (match_mod %>% filter(term == "DMF"))$estimate

[1] -0.2838299

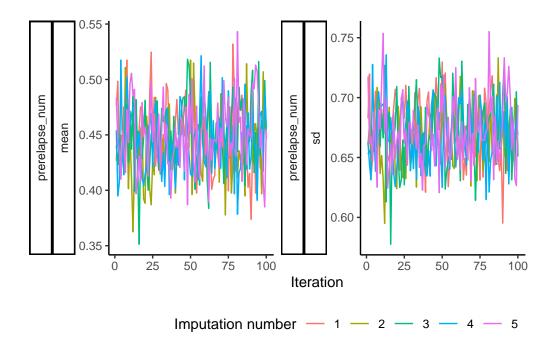

# Standard error
  (match_mod %>% filter(term == "DMF"))$std.error

[1] 0.1221876
```

1.2 Convergence checking

We can inspect convergence for the imputed variable prerelapse_num using a trace plot:

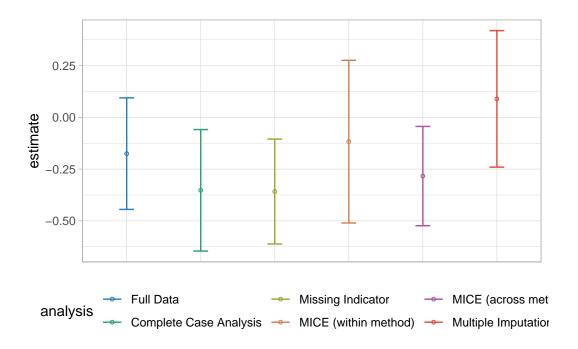

```
plot_trace(imp, vrb = "prerelapse_num")
```

1.3 Results

Analysis methods:

- Full Data: The treatment effect is estimated in the original data of N = 3000 patients where no missing values are present. This estimate can be used as a benchmark to compare the missing data methods.
- Complete Case Analysis: The treatment effect is estimated using all data from N = 946 patients that do not have any missing values.
- Missing Indicator: The treatment effect is estimated in the incomplete dataset of N=3000 patients. The propensity score model includes a missing indicator variable for each incomplete covariate.
- MICE (within method): A treatment effect is estimated within each imputed dataset using propensity score analysis. Using Rubin's rule, the five treatment effects are combined into a single treatment effect.
- MICE (ITE method): The missing covariates and potential outcomes are imputed simultaneously. Treatment effect estimates are derived by taking the average of the individualized treatment effect estimates Y|DMF Y|TERI.

2 Confounding adjustment using propensity score methods

The purpose of this document is to provide example R code that demonstrates how to estimate the propensity score and implement matching, stratification, weighting, and regression adjustment for the continuous propensity score. In this example using simulated data, we have two disease modifying therapies (DMT1 and DMT0) and the outcome is the number of post-treatment multiple sclerosis relapses during follow-up. We will estimate the average treatment effect in the treated (ATT) using propensity score matching, stratification, and weighting. We will estimate the average treatment effect in the population (ATE) using regression adjustment for the continuous propensity score. The treatment effects can be interpreted as annualized relapse rate ratios (ARR).

We consider an example dataset with the following characteristics:

head(dat)

age remale previo				
ago remare provi	OMTefficacy preme	ealcalcost	numSymptoms	prerelapse_num
1: 50 1	None	3899.61	1	1
2: 51 0	None	9580.51	1	0
3: 56 0	None	4785.89	1	0
4: 44 1	None	8696.80	1	1

6: 28 1	None	5435.57	1	0
treatment y	years Isco	ore		
1: DMT1 0 1.78	3507871 Moderate	A1		
2: DMT1 0 0.01	1368925 High	A1		
3: DMT1 2 3.25	5530459 High	A1		
4: DMT1 2 5.73	3853525 Neutr	ral		
5: DMT1 0 1.31	1143053 High	A1		
6: DMT1 0 0.59	9137577 Moderate	AO		

3 Comparing baseline characteristics

- $\bullet\,$ DMT1 is the treatment group and DMT0 is the control group
- prevDMTefficacy is previous DMT efficacy (none, low efficacy, and medium/high efficacy)
- prerelapse_num is the number of previous MS relapses

DMT0	DMT1
2300	7700
51.39(8.32)	44.25 (9.79)
$1671\ (72.65)$	5915 (76.82)
1247 (54.22)	3171 (41.18)
$261\ (11.35)$	858 (11.14)
792 (34.43)	3671 (47.68)
$0.39 \ (0.62)$	0.46 (0.68)
	2300 51.39 (8.32) 1671 (72.65) 1247 (54.22) 261 (11.35) 792 (34.43)

4 Estimating the propensity score

4.1 Logistic regression

We sought to restore balance in the distribution of baseline covariates in patients treated with DMT1 (index treatment) and DMT0 (control tratment). We fit a multivariable logistic regression model in which treatment was regressed on baseline characteristics including age, sex, previous DMT efficacy, and previous number of relapses.

```
# Fit logistic regression model
  ps.model <- glm(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                  data = dat, family = binomial())
  # Summary of logistic regression model
  summary(ps.model)
Call:
glm(formula = treatment ~ age + female + prevDMTefficacy + prerelapse_num,
    family = binomial(), data = dat)

5.3 Estimating the ATT

We can estimate the ATT in the matched sample using Poisson regression in which the number of post-treatment relapses is regressed on treatment status and follow-up time for each patient (captured by the variable years). More details are provided at https://cran.r-project.org/web/packages/MatchIt/vignettes/estimating-effects.html.

```
data = matched.data,
              weights = weights)
  # Treatment effect estimation
  opt.comp <- comparisons(opt.fit,</pre>
                           variables = "treatment",
                           vcov = ~subclass,
                           newdata = subset(matched.data, treatment == "DMT1"),
                           wts = "weights",
                           transform_pre = "ratio")
  opt.comp |> tidy()

                                                    7.59 3.21e-14
                                                                     0.564
                                                                             0.958
# ... with abbreviated variable names 1: estimate, 2: std.error, 3: statistic,
    4: conf.low, 5: conf.high
```

As indicated in the summary output above, the annualized relapse rate ratio for DMT1 vs DMT0 among patients treated with DMT0 (ATT) is given as 0.76 with a 95% confidence interval ranging from 0.56 to 0.96.

6 Propensity score stratification

6.1 Divide sample into quintiles of propensity scores

We will form five mutually exclusive groups of the estimated propensity score.

6.2 Assess balance within each propensity score stratum

Within each propensity score stratum, treated and control patients should have similar values of the propensity score and the distribution of baseline covariates should be approximately balanced between treatment groups.

6.2.1 Propensity Score Stratum #1

6.3 Estimating and pooling of stratum-specific treatment effects

The overall ATT across strata can be estimated by weighting stratum-specific estimates by the proportion of treated patients in each stratum over all treated patients in the sample.

We first define a function att.strata.function() to calculate stratum-specific estimates of the treatment effect:

```
att.strata.function <- function(data, stratum, confint = TRUE) {</pre>
  fit <- glm("y ~ treatment + offset(log(years))",</pre>
      family = poisson(link = "log"),
      data = data %>% filter(ps.strata == stratum))
  arr <- round(as.numeric(exp(coef(fit)["treatmentDMT1"])), digits = 3)</pre>
  11 <- ul <- NA
  if (confint) {
    11 <- round(exp(confint(fit))["treatmentDMT1",1], digits = 3)</pre>
    ul <- round(exp(confint(fit))["treatmentDMT1",2], digits = 3)</pre>
  }
  return(c("stratum" = stratum,
            "arr" = arr,
            "ci_lower" = 11,
            "ci_upper" = ul))
}
arr.strata <- as.data.frame(t(sapply(1:5, att.strata.function, data = dat)))</pre>
arr.strata
```

```
stratum
            arr ci_lower ci_upper
1
        1 0.904
                    0.760
                             1.076
2
        2 0.822
                    0.696
                             0.975
3
        3 0.798
                    0.666
                             0.961
4
        4 0.716
                    0.587
                             0.881
        5 0.589
                             0.761
                    0.463
```

Subsequently, we define a function weights.strata.function() to calculate the weights for each stratum. The weight is the proportion of treated patients in each stratum over all treated patients in the sample:

```
weights.strata.function <- function(data, stratum) {</pre>
    n_DMT1_stratum <- nrow(data %>% filter(ps.strata == stratum & treatment == "DMT1"))
    n_DMT1_all <- nrow(data %>% filter(treatment == "DMT1"))
    weight <- n_DMT1_stratum/n_DMT1_all</pre>
    return(c("stratum" = stratum, "weight" = weight))
  }
  weights.strata <- as.data.frame(t(sapply(1:5, weights.strata.function, data = dat)))</pre>
  weights.strata
 stratum
             weight
        1 0.1429870
1
2
        2 0.1815584
3
        3 0.2076623
        4 0.2244156
        5 0.2433766
  # Create table with ARRs and weights for each PS stratum
  arr.weights.merged <- merge(arr.strata, weights.strata, by = "stratum")</pre>
  # Calculate the weighted ARR for each stratum
  arr.weights.merged <- arr.weights.merged %>%
    mutate(weighted.arr = as.numeric(arr) * weight)
  # Sum the weighted ARRs across strata to get the overall ATT
  sum(arr.weights.merged$weighted.arr)
```

[1] 0.7482462

We now define a new function ps.stratification.bootstrap() that integrates estimation of the ATT and the PS weights for bootstrapping purposes:

We can now estimate the treatment effect and its confidence interval using the bootstrap procedure:

```
median(arr.stratification.boot$t)

[1] 0.7558609

# Bootstrapped ARR 95% CI
quantile(arr.stratification.boot$t[,1], c(0.025, 0.975))

2.5% 97.5%
0.6835885 0.8362947
```

7 Propensity score weighting

7.1 Calculate propensity score weights for ATT

Propensity score weighting reweights the study sample to generate an artificial population (i.e., pseudo-population) in which the covariates are no longer associated with treatment, thereby removing confounding by measured covariates. For the ATT, the weight for all treated patients is set to one. Conversely, the weight for patients in the control group is set to the propensity score divided by one minus the propensity score, that is, (PS/(1 - PS)). We estimated stabilized weights to address extreme weights.

```
library(WeightIt)
  w.out <- weightit(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                    data = dat,
                    method = "ps",
                    estimand = "ATT")
                    #stabilize = TRUE)
  w.out
A weightit object

7.3 Estimate the ATT

One way to estimate the ATT is to use the survey package. The function <code>svyglm()</code> generates model-robust (Horvitz-Thompson-type) standard errors by default, and thus does not require additional adjustments.

As indicated above, propensity score weighting yielded an ATT estimate of 0.71 (95% CI: 0.62; 0.8).

An alternative approach is to use glm() to estimate the treatment effect and calculate robust standard errors.

```
# Alternative way to estimate treatment effect
  weighted.fit2 <- glm(y ~ treatment + offset(log(years)),</pre>
                family = poisson(link = "log"),
                data = dat,
                weights = w.out$weights)
  # Extract the estimated ARR
  exp(coef(weighted.fit2))["treatmentDMT1"]
treatmentDMT1
   0.7083381
  # Calculate robust standard error and p-value of the log ARR
  coeftest(weighted.fit2, vcov. = vcovHC)["treatmentDMT1",]
                 Std. Error
                                  z value
                                               Pr(>|z|)
     Estimate
-3.448337e-01 6.442745e-02 -5.352280e+00 8.685284e-08
  # Derive 95% confidence interval of the ARR
  exp(lmtest::coefci(weighted.fit2,
         level = 0.95, # 95% confidence interval
         vcov. = vcovHC)["treatmentDMT1",])
   2.5 %
             97.5 %
0.6243094 0.8036767
```

Using this approach, the ATT estimate was 0.71 (95% CI: 0.62; 0.8).

8 Regression adjustment for the propensity score for the ATE

In this approach, a regression model is fitted to describe the observed outcome as a function of the received treatment and the estimated propensity score:

```
ps.reg.fit <- glm(y ~ treatment + ps + offset(log(years)),</pre>
                 family = poisson(link = "log"),
                 data = dat)
  summary(ps.reg.fit)
Call:
glm(formula = y ~ treatment + ps + offset(log(years)), family = poisson(link = "log"),
   data = dat)
Deviance Residuals:
   Min 1Q Median
                           3Q
                                  Max
-2.0160 -0.7336 -0.4441 -0.1352
                               4.2634

10 Effect Modification Analysis within the Propensity score Framework

First, we need to install the R package simcausal, which can be obtained from GitHub:

```
devtools::install_github('osofr/simcausal', build_vignettes = FALSE)
```

We will use the following data-generation model:

```
require(simcausal)
D <- DAG.empty()</pre>
D \leftarrow D +
  node("age", distr = "rnorm",
       mean = 2, sd = 4) +
  node("gender", distr = "rbern",
       prob = plogis(4)) +
  node("education", distr = "rbern",
       prob = plogis(3 + 5* age)) +
  node("diet", distr = "rbern",
       prob = plogis(1 -3 * education)) +
  node("income", distr = "rbern",
       prob = plogis(2 - 5 * education - 4 * age)) +
  node("smoking", distr = "rbern",
       prob = plogis(1 + 1.2 * gender + 2 * age)) +
  node("hypertension", distr = "rbern",
       prob = plogis(1 + log(3) * diet +
                        log(1.3) * age +
                        log(3.5) * smoking +
                        log(0.5) * gender))
Dset <- set.DAG(D)</pre>
plotDAG(Dset)
```

We can now generate an example dataset:

```
Obs.Data <- sim(DAG = Dset, n = 50000, rndseed = 123)
Obs.Data$smoking <- as.character(Obs.Data$smoking)
Obs.Data$income <- as.factor(Obs.Data$income)
Obs.Data$income <- relevel(Obs.Data$income, ref = "1")</pre>
```

Sample data from the hypothetical example of association between hypertension and smoking, where other variables such as income, age [centered], gender, education and diet also plays a role in the data generation process.

	age	gender	education	diet	income	smoking	hypertension
34901	12.288936	1	1	1	0	1	1
149	10.400436	1	1	0	0	1	1
10060	2.991820	1	1	0	0	1	0
22220	-4.311952	0	0	0	1	0	1
9979	-6.435549	0	0	0	1	0	1

10.1 Effect measure assessment via adding interaction term

Below, we estimate a logistic regression model to assess whether the effect of smoking (the exposure) on hypertension is modified by income. The covariates age and gender are confounders.

```
exp = TRUE)
results.model
```

	exp(Est.)	2.5%	97.5%	z val.	p
(Intercept)	5.46	4.37	6.82	14.97	0.00
smoking1	2.93	2.60	3.30	17.69	0.00
income0	0.48	0.41	0.57	-8.28	0.00
age	1.29	1.27	1.31	36.77	0.00
gender	0.54	0.43	0.67	-5.55	0.00
smoking1:income0	1.27	1.04	1.56	2.33	0.02

Standard errors: MLE

The interaction term in results.model is statistically significant.

Presentation of effect measures

We can generate a summary report from aforementioned effect modification analysis. The table below depicts the adjusted odds ratios for income levels (high = 0, and low = 1)

```
Measures Estimates
                                                    CI.11
                                                               CI.ul

                                                       NA
                                                                 NA
2
                                OR01 2.9301604 2.6010653 3.3008937
                                OR10 0.4832932 0.4068652 0.5740780
3
                                OR11 1.7997639 1.6334908 1.9829619
5 OR(smoking1 on outcome [income0==0] 2.9301604 2.6010653 3.3008937
6 OR(smoking1 on outcome [income0==1] 3.7239584 3.1434919 4.4116118
7
                Multiplicative scale 1.2709060 1.0385052 1.5553143
8
                                RERI -0.6136898 -0.9754808 -0.2905171
```

10.2 Effect measure assessment via stratified approach

This approach involves estimating a regression model in different strata of the effect modifier income:

The table below summarizes the adjusted odds ratios for smoking across the different income levels (low = 1, and high = 0) as obtained using the stratified approach.

```
Value of income exp(Est.) 2.5% 97.5% z val. p
[1,] 1 3.066878 2.707961 3.473366 17.64728 1.067842e-69
[2,] 0 3.590260 3.023124 4.263792 14.57113 4.287200e-48
```

Note that we can obtain the same results by estimating a regression model with an interaction term between the modifier and all covariates:

10.3 Interaction

Assessment of interaction between smoking and income. We estimate a logistic regression model where

- Outcome: hypertension
- Exposure variables: smoking and income
- Confounders: age, gender, and education

An interaction term of smoking and income is added.

```
exp(Est.)
                               2.5%
                                         97.5%
                                                   z val.
                                                                      р
(Intercept)
                5.6937765 4.5570175 7.1141027 15.3077121 6.791105e-53
smoking1
                3.3452459 2.9505339 3.7927612 18.8503257 2.920389e-79
income0
                1.0908060 0.8506311 1.3987941 0.6849951 4.933470e-01
                1.2981524 1.2804814 1.3160673 37.3150071 9.371499e-305
age
                0.5366777 0.4313229 0.6677666 -5.5815569 2.383750e-08
gender
                0.4233969 0.3502014 0.5118909 -8.8749618 6.995745e-19
education
smoking1:income0 1.1022535 0.8968615 1.3546825 0.9253438 3.547871e-01
```

The interaction term between income and smoking is, however, not statistically significant.

Presentation of effect measures

Summary report from an interaction analysis when investigating association between two exposure variables (smoking and income) and hypertension. Below, CI.11 and CI.ul depict the lower and upper limits of the 95 percent confidence intervals, $\mathtt{OR11} = OR_{A=1,M=1}$, $\mathtt{OR10} = OR_{A=1}$, $\mathtt{OR01} = OR_{M=1}$ and $\mathtt{OR00}$ captures the reference.

11 Dealing with irregular and informative visits

We first load the required packages

```
library(dplyr)
library(broom)
library(ggplot2)
library(mice)
```

11.1 Example dataset

In this example dataset, we have a discrete outcome y that is affected by its baseline value edss, age, sex, and the treatment duration time.

```
set.seed(9843626)
dataset <- sim_data_EDSS(npatients = 500,</pre>
                          ncenters = 10,
                          follow_up = 12*5, # Total follow-up (number of months)
                          sd_a_t = 0.5,  # DGM - Within-visit variation in EDSS scores
                          baseline_EDSS = 1.3295,  # DGM - Mean baseline EDDS score
                          sd_alpha_ij = 1.46,  # DGM - Between-subject variation in base
                          sd_beta1_j = 0.20,  # DGM - Between-site variation in baseline
                          mean_age = 42.41,
                          sd_age = 10.53,
                         min_age = 18,
                          beta_age = 0.05, # DGM - prognostic effect of age
                          beta_t = 0.014,  # DGM - prognostic effect of time
                          beta_t2 = 0,  # DGM - prognostic effect of time squared
                          delta_xt = 0, # DGM - interaction treatment time
                          delta_xt2 = 0, # 0.0005
                                                   # DGM - interaction treatment time2
                          p_female = 0.75,
                          beta_female = -0.2 , ## DGM - prognostic effect of male sex
                          delta_xf = 0, ## DGM - interaction sex treatment
```

We remove y according to the informative visit process that depends on the received treatment, gender, and age.

```
dataset_visit <- censor_visits_a5(dataset, seed = 12345) %>%
  dplyr::select(-y) %>%
  mutate(time_x = time*x)
```

In the censored data, a total of 17 out of 5000 patients have a visit at time=60.

11.2 Estimation of treatment effect

We will estimate the marginal treatment effect at time time=60.

11.2.1 Original data

11.2.2 Doubly-weighted marginal treatment effect

```
obsdat60 <- dataset_visit %>% mutate(visit = ifelse(is.na(y_obs),0,1)) %>% filter(time ==
gamma <- glm(visit ~ x + sex + age + edss, family = 'binomial', data = obsdat60)$coef</pre>
```

11.2.3 Multilevel multiple imputation

We impute the entire vector of y_obs for all 61 potential visits and generate 10 imputed datasets. Note: mlmi currently does not support imputation of treatment-covariate interaction terms.

```
imp <- impute_y_mice_31(dataset_visit, seed = 12345)</pre>
```

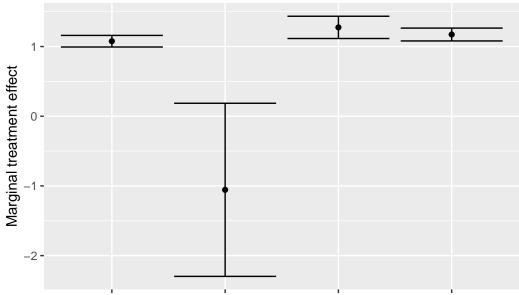

We can now estimate the treatment effect in each imputed dataset

```
Q[i] <- fit %>% filter(term == "x") %>% pull(estimate)
U[i] <- (fit %>% filter(term == "x") %>% pull(std.error))**2
}
fit_mlmi <- pool.scalar(Q = Q, U = U)</pre>
```

11.3 Reproduce the results using all data to compute the marginal effect with IIV-weighted

11.3.1 Doubly -weighted marginal treatment effect total

11.4 Results
