1 Confounding adjustment using propensity score methods

The purpose of this document is to provide example R code that demonstrates how to estimate the propensity score and implement matching, stratification, weighting, and regression adjustment for the continuous propensity score. In this example using simulated data, we have two disease modifying therapies (DMT1 and DMT0) and the outcome is the number of post-treatment multiple sclerosis relapses during follow-up. We will estimate the average treatment effect in the treated (ATT) using propensity score matching, stratification, and weighting. We will estimate the average treatment effect in the population (ATE) using regression adjustment for the continuous propensity score. The treatment effects can be interpreted as annualized relapse rate ratios (ARR).

We consider an example dataset with the following characteristics:

head(dat)

		£1-					
	age	remare	prevbMieiii	cacy prem	edicalcost	numsymptoms	<pre>prerelapse_num</pre>
1:	50	1]	None	3899.61	1	1

2 Comparing baseline characteristics

- $\bullet\,$ DMT1 is the treatment group and DMT0 is the control group
- prevDMTefficacy is previous DMT efficacy (none, low efficacy, and medium/high efficacy)
- prerelapse_num is the number of previous MS relapses

	DMT0	DMT1
n	2300	7700
age (mean (SD))	51.39(8.32)	44.25 (9.79)
female = 1 (%)	$1671\ (72.65)$	5915 (76.82)
prevDMTefficacy (%)		
None	1247 (54.22)	3171 (41.18)
Low_efficacy	$261\ (11.35)$	858 (11.14)
Medium_high_efficacy	792 (34.43)	3671 (47.68)
prerelapse_num (mean (SD))	0.39 (0.62)	0.46 (0.68)

3 Estimating the propensity score

3.1 Logistic regression

We sought to restore balance in the distribution of baseline covariates in patients treated with DMT1 (index treatment) and DMT0 (control tratment). We fit a multivariable logistic regression model in which treatment was regressed on baseline characteristics including age, sex, previous DMT efficacy, and previous number of relapses.

```
# Fit logistic regression model
  ps.model <- glm(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                  data = dat, family = binomial())
  # Summary of logistic regression model
  summary(ps.model)
Call:
glm(formula = treatment ~ age + female + prevDMTefficacy + prerelapse_num,
    family = binomial(), data = dat)

# Extract propensity scores
dat$ps <- predict(ps.model, data = dat, type = "response")
```

3.2 Assessing overlap

We examined the degree of overlap in the distribution of propensity scores across treatment groups using histograms and side-by-side box plots.

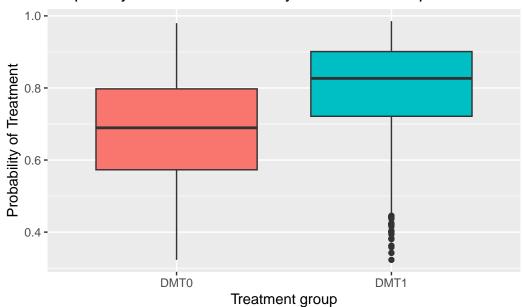

```
# Histogram
ggplot(dat, aes(x = ps, fill = as.factor(treatment), color = as.factor(treatment))) +
    geom_histogram(alpha = 0.3, position='identity', bins = 15) +
    facet_grid(as.factor(treatment) ~ .) +
    xlab("Probability of Treatment") +
    ylab("Count") +
    ggtitle("Propensity Score Distribution by Treatment Group") +
    theme(legend.position = "bottom", legend.direction = "vertical")
```

Propensity Score Distribution by Treatment Group

```
# Side-by-side box plots
ggplot(dat, aes(x=as.factor(treatment), y=ps, fill=as.factor(treatment))) +
    geom_boxplot() +
    ggtitle("Propensity Score Distribution by Treatment Group") +
    ylab("Probability of Treatment") +
    xlab("Treatment group") +
    theme(legend.position = "none")
```

Propensity Score Distribution by Treatment Group

```
# Distribution of propensity scores by treatment groups

4.3 Estimating the ATT

We can estimate the ATT in the matched sample using Poisson regression in which the number of post-treatment relapses is regressed on treatment status and follow-up time for each patient (captured by the variable years). More details are provided at https://cran.r-project.org/web/packages/MatchIt/vignettes/estimating-effects.html.

```
data = matched.data,
              weights = weights)
  # Treatment effect estimation
  opt.comp <- comparisons(opt.fit,</pre>
                           variables = "treatment",
                           vcov = ~subclass,
                           newdata = subset(matched.data, treatment == "DMT1"),
                           wts = "weights",
                           transform_pre = "ratio")
  opt.comp |> tidy()

                                           <dbl>
                                                                     <dbl>
                                                                             dbl>
1 response treatment mean(DMT1~
                                   0.761
                                           0.100
                                                    7.59 3.21e-14
                                                                     0.564
                                                                             0.958
# ... with abbreviated variable names 1: estimate, 2: std.error, 3: statistic,
    4: conf.low, 5: conf.high
```

As indicated in the summary output above, the annualized relapse rate ratio for DMT1 vs DMT0 among patients treated with DMT0 (ATT) is given as 0.76 with a 95% confidence interval ranging from 0.56 to 0.96.

5 Propensity score stratification

5.1 Divide sample into quintiles of propensity scores

We will form five mutually exclusive groups of the estimated propensity score.

5.2 Assess balance within each propensity score stratum

Within each propensity score stratum, treated and control patients should have similar values of the propensity score and the distribution of baseline covariates should be approximately balanced between treatment groups.

5.3 Estimating and pooling of stratum-specific treatment effects

The overall ATT across strata can be estimated by weighting stratum-specific estimates by the proportion of treated patients in each stratum over all treated patients in the sample.

We first define a function att.strata.function() to calculate stratum-specific estimates of the treatment effect:

```
att.strata.function <- function(data, stratum, confint = TRUE) {</pre>
  fit <- glm("y ~ treatment + offset(log(years))",</pre>
      family = poisson(link = "log"),
      data = data %>% filter(ps.strata == stratum))
  arr <- round(as.numeric(exp(coef(fit)["treatmentDMT1"])), digits = 3)</pre>
  11 <- ul <- NA
  if (confint) {
    11 <- round(exp(confint(fit))["treatmentDMT1",1], digits = 3)</pre>
    ul <- round(exp(confint(fit))["treatmentDMT1",2], digits = 3)</pre>
  }
  return(c("stratum" = stratum,
            "arr" = arr,
            "ci_lower" = 11,
            "ci_upper" = ul))
}
arr.strata <- as.data.frame(t(sapply(1:5, att.strata.function, data = dat)))</pre>
arr.strata
```

```
stratum
            arr ci_lower ci_upper
1
        1 0.904
                    0.760
                              1.076
2
        2 0.822
                    0.696
                             0.975
3
        3 0.798
                    0.666
                             0.961
4
        4 0.716
                    0.587
                             0.881
        5 0.589
                             0.761
                    0.463
```

Subsequently, we define a function weights.strata.function() to calculate the weights for each stratum. The weight is the proportion of treated patients in each stratum over all treated patients in the sample:

```
weights.strata.function <- function(data, stratum) {</pre>
    n_DMT1_stratum <- nrow(data %>% filter(ps.strata == stratum & treatment == "DMT1"))
    n_DMT1_all <- nrow(data %>% filter(treatment == "DMT1"))
    weight <- n_DMT1_stratum/n_DMT1_all</pre>
    return(c("stratum" = stratum, "weight" = weight))
  }
  weights.strata <- as.data.frame(t(sapply(1:5, weights.strata.function, data = dat)))</pre>
  weights.strata
 stratum
             weight
        1 0.1429870
1
2
        2 0.1815584
3
        3 0.2076623
        4 0.2244156
        5 0.2433766
  # Create table with ARRs and weights for each PS stratum
  arr.weights.merged <- merge(arr.strata, weights.strata, by = "stratum")</pre>
  # Calculate the weighted ARR for each stratum
  arr.weights.merged <- arr.weights.merged %>%
    mutate(weighted.arr = as.numeric(arr) * weight)
  # Sum the weighted ARRs across strata to get the overall ATT
  sum(arr.weights.merged$weighted.arr)
```

[1] 0.7482462

We now define a new function ps.stratification.bootstrap() that integrates estimation of the ATT and the PS weights for bootstrapping purposes:

We can now estimate the treatment effect and its confidence interval using the bootstrap procedure:

6 Propensity score weighting

6.1 Calculate propensity score weights for ATT

Propensity score weighting reweights the study sample to generate an artificial population (i.e., pseudo-population) in which the covariates are no longer associated with treatment, thereby removing confounding by measured covariates. For the ATT, the weight for all treated patients is set to one. Conversely, the weight for patients in the control group is set to the propensity score divided by one minus the propensity score, that is, (PS/(1 - PS)). We estimated stabilized weights to address extreme weights.

```
library(WeightIt)
  w.out <- weightit(treatment ~ age + female + prevDMTefficacy + prerelapse_num,
                    data = dat,
                    method = "ps",
                    estimand = "ATT")
                    #stabilize = TRUE)
  w.out
A weightit object

6.3 Estimate the ATT

One way to estimate the ATT is to use the survey package. The function <code>svyglm()</code> generates model-robust (Horvitz-Thompson-type) standard errors by default, and thus does not require additional adjustments.

As indicated above, propensity score weighting yielded an ATT estimate of 0.71 (95% CI: 0.62; 0.8).

An alternative approach is to use glm() to estimate the treatment effect and calculate robust standard errors.

```
# Alternative way to estimate treatment effect
  weighted.fit2 <- glm(y ~ treatment + offset(log(years)),</pre>
                family = poisson(link = "log"),
                data = dat,
                weights = w.out$weights)
  # Extract the estimated ARR
  exp(coef(weighted.fit2))["treatmentDMT1"]
treatmentDMT1
   0.7083381
  # Calculate robust standard error and p-value of the log ARR
  coeftest(weighted.fit2, vcov. = vcovHC)["treatmentDMT1",]
                 Std. Error
                                  z value
                                               Pr(>|z|)
     Estimate
-3.448337e-01 6.442745e-02 -5.352280e+00 8.685284e-08
  # Derive 95% confidence interval of the ARR
  exp(lmtest::coefci(weighted.fit2,
         level = 0.95, # 95% confidence interval
         vcov. = vcovHC)["treatmentDMT1",])
   2.5 %
             97.5 %
0.6243094 0.8036767
```

Using this approach, the ATT estimate was 0.71 (95% CI: 0.62; 0.8).

7 Regression adjustment for the propensity score for the ATE

In this approach, a regression model is fitted to describe the observed outcome as a function of the received treatment and the estimated propensity score:

```
ps.reg.fit <- glm(y ~ treatment + ps + offset(log(years)),</pre>
                 family = poisson(link = "log"),
                 data = dat)
  summary(ps.reg.fit)
Call:
glm(formula = y ~ treatment + ps + offset(log(years)), family = poisson(link = "log"),
   data = dat)
Deviance Residuals:
   Min 1Q Median
                           3Q
                                  Max
-2.0160 -0.7336 -0.4441 -0.1352
                               4.2634

9 Effect Modification Analysis within the Propensity score Framework

First, we need to install the R package simcausal, which can be obtained from GitHub:

```
devtools::install_github('osofr/simcausal', build_vignettes = FALSE)
```

We will use the following data-generation model:

```
require(simcausal)
D <- DAG.empty()</pre>
D \leftarrow D +
  node("age", distr = "rnorm",
       mean = 2, sd = 4) +
  node("gender", distr = "rbern",
       prob = plogis(4)) +
  node("education", distr = "rbern",
       prob = plogis(3 + 5* age)) +
  node("diet", distr = "rbern",
       prob = plogis(1 -3 * education)) +
  node("income", distr = "rbern",
       prob = plogis(2 - 5 * education - 4 * age)) +
  node("smoking", distr = "rbern",
       prob = plogis(1 + 1.2 * gender + 2 * age)) +
  node("hypertension", distr = "rbern",
       prob = plogis(1 + log(3) * diet +
                        log(1.3) * age +
                        log(3.5) * smoking +
                        log(0.5) * gender))
Dset <- set.DAG(D)</pre>
plotDAG(Dset)
```

We can now generate an example dataset:

```
Obs.Data <- sim(DAG = Dset, n = 50000, rndseed = 123)
```

9.1 Effect measure assessment via adding interaction term

Table 9.1: Sample data from the hypothetical example of association between hypertension and smoking, where other variables such as income, age [centered], gender, education and diet also plays a role in the data generation process.

age	gender	education	diet	income	smoking	hypertension
12.29	1	1	1	0	1	1
10.40	1	1	0	0	1	1
2.99	1	1	0	0	1	0
-4.31	0	0	0	1	0	1
-6.44	0	0	0	1	0	1

The estimates from results.model are as follows:

Table 9.2: Assessment of effect modification by income. The output shown from the logistic regression model in a odds ratio scale, where hypertnsion is the outcome, smoking is the exposure, age, gender are confounders, and main effect and interaction term of income and exposure are added. Here the interaction term is significant.

	Odds Ratio	2.5%	97.5%	z-value	p-value
(Intercept)	5.46	4.37	6.82	14.97	< 2e-16
smoking1	2.93	2.60	3.30	17.69	< 2e-16
income0	0.48	0.41	0.57	-8.28	< 2e-16
age	1.29	1.27	1.31	36.77	< 2e-16
gender	0.54	0.43	0.67	-5.55	2.9e-08
smoking1:income0	1.27	1.04	1.56	2.33	0.02

Table 9.3: Summary report from an effect modification analysis by income when investigating association between one exposure variable (smoking) and outcome hypertension. Adjusted odds ratios are reported for income levels (high' = 0, andlow' = 1)

Measures	Estimates	CI.ll	CI.ul	р
OR(smoking1 on outcome [income0==0]	2.93	2.60	3.30	0.00
OR(smoking1 on outcome [income0==1]	3.72	3.14	4.41	0.00
Multiplicative scale	1.27	1.04	1.56	0.02

Presentation of effect measures

10 Dealing with irregular and informative visits

We first load the required packages

```
library(dplyr)
library(broom)
library(ggplot2)
library(mice)
```

10.1 Example dataset

In this example dataset, we have a discrete outcome y that is affected by its baseline value edss, age, sex, and the treatment duration time.

```
set.seed(9843626)
dataset <- sim_data_EDSS(npatients = 500,</pre>
                          ncenters = 10,
                          follow_up = 12*5, # Total follow-up (number of months)
                          sd_a_t = 0.5,  # DGM - Within-visit variation in EDSS scores
                          baseline_EDSS = 1.3295,  # DGM - Mean baseline EDDS score
                          sd_alpha_ij = 1.46,  # DGM - Between-subject variation in base
                          sd_beta1_j = 0.20,  # DGM - Between-site variation in baseline
                          mean_age = 42.41,
                          sd_age = 10.53,
                         min_age = 18,
                          beta_age = 0.05, # DGM - prognostic effect of age
                          beta_t = 0.014,  # DGM - prognostic effect of time
                          beta_t2 = 0,  # DGM - prognostic effect of time squared
                          delta_xt = 0, # DGM - interaction treatment time
                          delta_xt2 = 0, # 0.0005
                                                   # DGM - interaction treatment time2
                          p_female = 0.75,
                          beta_female = -0.2 , ## DGM - prognostic effect of male sex
                          delta_xf = 0, ## DGM - interaction sex treatment
```

We remove y according to the informative visit process that depends on the received treatment, gender, and age.

```
dataset_visit <- censor_visits_a5(dataset, seed = 12345) %>%
  dplyr::select(-y) %>%
  mutate(time_x = time*x)
```

In the censored data, a total of 17 out of 5000 patients have a visit at time=60.

10.2 Estimation of treatment effect

We will estimate the marginal treatment effect at time time=60.

10.2.1 Original data

10.2.2 Doubly-weighted marginal treatment effect

```
obsdat60 <- dataset_visit %>% mutate(visit = ifelse(is.na(y_obs),0,1)) %>% filter(time ==
gamma <- glm(visit ~ x + sex + age + edss, family = 'binomial', data = obsdat60)$coef</pre>
```

10.2.3 Multilevel multiple imputation

We impute the entire vector of y_obs for all 61 potential visits and generate 10 imputed datasets. Note: mlmi currently does not support imputation of treatment-covariate interaction terms.

```
imp <- impute_y_mice_31(dataset_visit, seed = 12345)</pre>
```

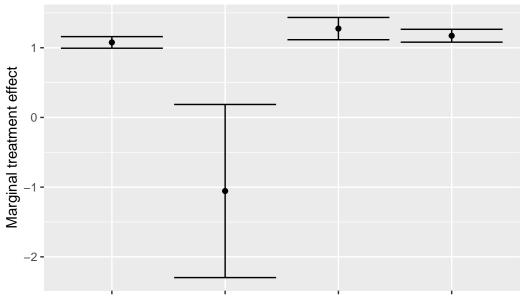

We can now estimate the treatment effect in each imputed dataset

```
Q[i] <- fit %>% filter(term == "x") %>% pull(estimate)
U[i] <- (fit %>% filter(term == "x") %>% pull(std.error))**2
}
fit_mlmi <- pool.scalar(Q = Q, U = U)</pre>
```

10.3 Reproduce the results using all data to compute the marginal effect with IIV-weighted

10.3.1 Doubly -weighted marginal treatment effect total

10.4 Results

Doubly weighted all times combuinbed weighteld the Multiple Imputation t=6 Reference method
